Introduction

History

Molecular dynamics (MD) simulations have been evolved as powerful tools to explore atomic level of mechanisms, which are usually out the scopes of current experimental tools. Molecular dynamics are numeric tools based on the Newton's equations of motions for N -body system simulations by iteratively updating particle forces and system potential energies composed by inter-atomic/intra-atomic potentials or mechanic force fields. During MD simulations, coordinates, velocities, forces and potential energies are calculated every iterative step, whose temporal gap between each other is called "time step". The smaller the time step, the more accurate but more computational intensive the simulation is.

The original idea of MD simulations came up in 1950s in theoretical physics, but later it was also introduced to chemical, material science, and biological molecular simulations. Later in 1960s, Lennard-Jones potentials were introduced for lipid simulations (Rahman, 1964). However, at that time, computational power limited the simulation system size and time scale.

McCammon *et al.* (1977) reported the first MD simulation study of the dynamics of a protein bovine pancreatic trypsin inhibitor. Ever since then, more and more researches were carried out, and MD simulation has developed as a powerful tool in studying macromolecules and their interactions. Ogata *et al.* (2013) reported a work using MD simulation to study the photosynthesis system II, which is a signal that we are embracing a period where simulations of complicated systems become possible.

Anton, as well as Anton II, created by D.E. Shaw's group, as a specialized simulation machine, outperforms any other same scale computational devices in speed and efficiency. It was successfully used to perform long time scale all atomic simulations (Lindorff-Larsen *et al.*, 2011; Piana *et al.*, 2011; Shaw *et al.*, 2010).

As the knowledge of chemistry and physics increase, we would know much more about the micro-world behaviors. Along with the development of hardware of computers and the algorithms, we are now towards a theoretic biology era, when every experiment could be performed *in silico* rather than by bench works. This goal, using computers to simulate every aspect and every level of life sciences, is difficult to imagine but would be finally achieved.

Background/Fundamentals

Molecular dynamics (MD) simulation is the computer based N -Body simulation of systems containing atoms and molecules. In MD simulation, the system components are left to interact together for a predetermined period, while the system physical properties are monitored. Those properties are either macroscopic system properties, $\{V$ (volume), P (pressure), T (temperature), N (number of particles) $\}$, or microscopic system properties, $\{v_i$ (velocities), r_i (positions) $\}$.

Ensemble and trajectory

The output of the simulation comes in the form of ensemble of frames. All frames share the same macroscopic/thermodynamic state but may differ in the microscopic states. Each frame represents the system at a specific point of time (a specific microscopic state). If the ensemble is sequence (time) dependent, it is called a trajectory. In this case, the trajectory represents the time-dependent evolution of the system.

Canonical ensemble (NVT)

The canonical ensemble contains all possible states in thermal equilibrium with a heat bath. The system remains in the absolute temperature T but may exchange energy with the heat bath. Three parameters of the system are fixed throughout the simulation: the absolute temperature (T), the number of atoms (N), and the volume (V). T is the most influential parameter on the system states among them.

Micro canonical ensemble (NVE)

The micro canonical ensemble represents an isolated system. No change in mass/number of atoms (N), Volume (V), nor exchange of Energy (E) is allowed.

Isothermal–isobaric ensemble (NPT)

The system has a fixed temperature (T), hence it is isothermal, and fixed pressure (P), hence it is isobaric.

Force field

Nearly all the simulation methods rely on force field for calculation. Force field, a potential energy (Eq. (1)) field in atomic and molecular level, describes the topology and motion behavior of atoms in molecules. When we use force field to describe the properties of molecules, spectrum constant force field and empirical potential function force field are often introduced. There are also Dreiding force field and universal force field (Mayo *et al.*, 1990; Setubal and Meidanis, 1997) which are not discussed here in detail.

$$E_{total} = E_{kinetic} + U_{potential} \quad (1)$$

In spectrum constant field, the energy is simply linked with distance between two atoms. (See Eq. (2), K_i is a constant measured by spectrum data, ΔR_i is the distance between atom i and atom j .) This only applies for simple molecules such as water molecules.

$$E_{vibrant} = \frac{1}{2} \sum_i K_i (\Delta R_i)^2 \quad (2)$$

For multi-atom molecules, internal coordinates are introduced. Four internal coordinates are commonly used as depicted in Fig. 1. These four coordinates (bond stretching, bond angle, torsion angle and out-of-plane angle) do not affect the overall movements in the space, but they are enough to describe the internal motion of the molecules.

In other simulation methods, potential energy is composed by several terms: non-binding potential, bonding stretching term potential, angle bending term potential, torsion (dihedral) angle term potential, out-of-plane bending term potential, columbic interaction term potential (Frenkel and Smit, 2002). For many force fields, the calculations are based on the terms mentioned above. The most frequently applied non-binding potential is described by Lennard-Jones (LJ) potential force. (See Eq. (3), r is distance between two atoms, ε and σ are atomic specific constants).

$$U_r = 4\varepsilon \left[\left(\frac{\sigma}{r} \right)^{12} - \left(\frac{\sigma}{r} \right)^6 \right] \quad (3)$$

In Eq. (3), for the U_r of two atoms A and B, the parameter σ could be approximated by the following equation. (See Eq. (4)).

$$\sigma_{AB} = \frac{1}{2}(\sigma_A + \sigma_B), \varepsilon_{AB} = \sqrt{\varepsilon_A \varepsilon_B}; \quad (4)$$

$$U_b = \frac{1}{2} \sum_i k_b (r_i - r_i^0)^2 \quad (5)$$

Eq. (5) is a common expression of bonding stretching term potential function (a simple harmonic vibration model). r_i is the bond length of the no. i th bond, while r_i^0 is the average bond length of the bond i :

$$U_\theta = \frac{1}{2} \sum_i k_\theta (\theta_i - \theta_i^0)^2 \quad (6)$$

Fig. 1 Four types of internal coordinates used to potential energies in MD force fields. The 4 types of internal coordinates are bond, angle, dihedral angle, and out-of-plane angle.

$$U_{\tau} = \frac{1}{2} \sum_i [V_1(1 + \cos\tau) + V_2(1 - \cos 2\tau) + V_3(1 + \cos 3\tau)] \quad (7)$$

Common bending angle term potential is defined by Eq. (6). θ_i is the angle between the two bonds on the atom i . The Eq. (7) concerns the torsion angle term potential energy. While τ is torsion angle using the no. i atom as the center. V_1 , V_2 and V_3 are force constants.

$$U_{\alpha} = \frac{1}{2} \sum_i k_{\alpha} \alpha^2 \quad (8)$$

Eq. (8) is out-of-plane term potential energy function. k_{α} is a constant and α is the out-of-plane angle.

$$U_{\text{coulombic}} = \sum_{ij} \frac{q_i \cdot q_j}{D \cdot r_{ij}} \quad (9)$$

This coulombic term potential energy is the electric energy between the no. i and no. j atom. D is dielectric constant, and r_{ij} is the distance between two atoms. q is the electric charge of atoms.

Most famous classical force fields used for modeling of *Macromolecules* are GROMOS (Groningen Molecular Simulation) (Christen *et al.*, 2005; van Gunsteren *et al.*, 1996), AMBER (Assisted Model Building with Energy Refinement) (Cornell *et al.*, 1995), and CHARMM (Chemistry at HARvard Macromolecular Mechanics) (Brooks *et al.*, 1983). CHARMM can also be used for *small molecules*. OPLS (Optimized Potentials for Liquid Simulations) (Jorgensen *et al.*, 1996; Jorgensen and Tirado-Rives, 1988) is used to model *liquids* and it can as well be used in *Energy minimization*.

Another group of force fields called second generation force fields, integrates more complicated quantum mechanics and experimental results to pursuit more precise simulation. Some examples are CFF91, PCFF, CFF95, MMFF94 (Halgren, 1996), etc. There are also some special force fields (such as COMPASS and Gay-Berne) “costumed” for specific molecules, and thus are not explained in detail here.

Methodology

The total energy of a system is the sum of both kinetic and potential energies. The kinetic energy can be calculated from the atoms/particles velocities, while the potential energy is related to the positions of all atoms/particles in the 3 directions (that is $3N$, where N is number of atoms). This is too big number of parameters to have any analytical solution. Therefore, numerical methods only can be used to calculate.

Integrators

The MD simulation is based on Newton's second law of motion, ($F=ma$), where F is the force affecting a particle, m is the particle mass and a is its acceleration. Most integrators assume that the velocity and acceleration can be approximated using Taylor's expansion. From particles' relative position (r), velocity (v), and acceleration (a), the time series time-dependent evolution of the system can be predicted step wise.

$$r(t + \delta t) = r(t) + v(t)\delta t + \frac{1}{2}a(t)\delta t^2 + \dots$$

$$v(t + \delta t) = v(t) + a(t)\delta t + \frac{1}{2}b(t)\delta t^2 + \dots$$

$$a(t + \delta t) = a(t) + b(t)\delta t + \dots$$

Most famous integrators are *Verlet*, *Leapfrog*, and *Velocity Verlet*.

Methods to Overcome Limitations and Decrease Load

The calculation complexity of the MD simulation problem is a $O(n^2)$ problem. This limits the ability to simulate large systems. Methods exist to minimize the computational load. Some of them are mentioned next sections.

Neighborhood list

Having a neighborhood list for each atom, reduces the calculation complexity from $O(n^2)$ to $O(n)$. The neighborhood list needs to be updated periodically, in a suitable frequency: Neither too infrequent so that important updates may be missed, nor so frequent that the calculation efficiency gained in reduced complexity calculations may be lost.

Periodic boundary check (PBC)

To neglect the solvent surface tension effect, there are two options: having an infinite amount of solvent, which is impractical, or to have the periodic boundary check (PBC). In the PBC, every atom is considered replicated to image atoms in all directions.

PME, PPPM

Another advantage of the PBC is the ability to model long interactions as periodic interactions to be solved in the frequency domain. Particle Mesh Ewald summation (PME) is an efficient way to achieve this goal which depends on sorting and calculating image atoms in a certain order that simplifies the calculation. Another advancement of PME method is “Particle-Particle, Particle-Mesh” (PPPM) method. In this method, the short range interactions are calculated as particle-particle interactions, while for the long range interactions, it is calculated as follows: first, all particles effect is approximated to a set of charges spread on a mesh. The long range interactions with the mesh are calculated efficiently in the frequency domain.

Advanced Techniques

The large-scale conformation differences between meta-stable states of macromolecules are often separated by high energy barriers which are unlikely accessible through conventional MD simulations. Based on the transition state theory, there is an exponential relationship between the time scale of state transition and the height of an energy barrier (Huang, 1987). Therefore, the rare dynamics events of interest, e.g., the folding process of a polypeptide, are often happening in a rather large time scale (Kubelka *et al.*, 2004). For example, according to Kubelka *et al.* (2004) the folding time limit of a generic single-domain protein from unfolded to folded state, could be expressed as following: $N/100 \mu s$, where N is the number of residues in the protein. In order to obtain a statistical meaningful transition free energies, multiple times trans-passing of the energy local minima are required based on the assumption of the ergodicity (Tolman, 1938) for conventional MD simulations, which probably requires extremely long simulation time. Therefore, for large proteins, using conventional MD simulations to sample the large energy barrier crossing events could be an impossible mission. However, a number of enhanced sampling methods, such as the replica exchange MD simulation (REMD) method (Sugita and Okamoto, 1999a), solute tempering (Liu *et al.*, 2005), Hamiltonian replica exchange MD (HREMD) (Liu *et al.*, 2005), Wang-Landau method and simulated tempering (ST) (Marinari and Parisi, 1992; Zhang *et al.*, 2015), have been developed to address the difficulties. Besides, other enhanced sampling methods, including umbrella sampling (Torrie and Valleau, 1977) and metadynamics (Laio and Parrinello, 2002), based on introduced bias potentials, could reconstruct the probability distribution along one or a few CVs (Sutto *et al.*, 2012). What's more, the combinations of these methods are also proved to be efficient tools to explore the free energy surface (FES). For example, the hybrid Hamiltonian method by introducing the Generalized Born energy for polar solvation energy calculations, is a useful tool to quickly reconstruct the FES which is similar to the standard REMD simulation (Mu *et al.*, 2007). Also the combination of parallel tempering with metadynamics by Bussi *et al.* is also proved to be powerful (Bussi *et al.*, 2006b).

Umbrella sampling

Umbrella sampling (Torrie and Valleau, 1974, 1977), as an enhanced sampling method, could sample the conformational dynamics along reaction coordinates thus we could estimate the relative free energy of different states along the reaction coordinates. A reaction coordinate (ξ) could be a kind of continuous parameter which could describe the system from a higher dimensional space. If the reaction coordinate is good enough to differentiate distinct states, by biasing the system along the reaction coordinate, thus we would calculate the free energy differences between the states.

In a general umbrella sampling scheme, multiple windows were set with initial structures with different reaction coordinate values. A bias potential is applied to each window (Eq. (10)) according to a harmonic bias function (Eq. (11)) or an adaptive bias function (Kästner, 2011). Therefore, the system in each window would be constrained to sample a narrow phase space along the reaction coordinate to ensure potential energy distribution overlap between adjacent windows. After the simulations, a post-processing method, weighted histogram analysis method (WHAM) (Rosenberg, 1992), could recover the unbiased free energy by the umbrella integration. Multiple integration methods and biasing potential styles are existed, among them, WHAM as the integration method, harmonic bias potential as the biasing potential style are relatively widely used. The following part is a brief introduction to the general procedures of umbrella sampling using harmonic bias potential and WHAM post-processing method.

When we add a reaction coordinate dependent bias potential $\omega_i(\xi)$ to the system in a window, the total biased energy could be expressed as following:

$$E_{bias} = E_{unbias} + \omega_i(\xi) \quad (10)$$

where i represents the i th window of the umbrella sampling. The harmonic bias potential adding to the system is a simple bias potential expressed like this:

$$\omega_i(\xi) = \frac{1}{2} K (\xi - \xi_i)^2 \quad (11)$$

Here ξ_i works as a reference coordinate point. During the simulations, if the system is escaping the reaction coordinate, then a bias potential is added to push the system back.

To calculate the unbiased free energy, we need to obtain the unbiased distribution of the reaction coordinate, according the following equation:

$$P_i^u(\xi) = \frac{\int \exp[-\beta E(r)] \delta[\xi'(r) - \xi] d^{N_r}}{\int \exp[-\beta E(r)] d^{N_r}} \quad (12)$$

Furthermore, the unbiased probability $P_i^u(\xi)$ could be determined by:

$$P_i^u(\xi) = P_i^b(\xi) \exp[\beta \omega_i(\xi)] \exp[-\beta \omega_i(\xi)] \quad (13)$$

From the simulation in each window, the biased probability $P_i^b(\xi)$ is known, and the free energy of the window thus could be induced by:

$$E_{unbias} = - \left(\frac{1}{\beta} \right) \ln P_i^b(\xi) - \omega_i(\xi) + F_i \quad (14)$$

where F_i is a constant which could be solved by self-iteration until a convergence reached (Banavali and Roux, 2005). Besides, the unbiased free energy could be combined by all the windows to produce a whole free energy along the reaction coordinate.

Metadynamics simulation

Different from the conventional MD simulations, metadynamics (Laio and Parrinello, 2002) adopts gaussian-like bias to bypass high energy barriers in FES. By adding bias potentials, the predefined collective variables (CVs), metadynamics sampling could reconstruct the FES based on the biased CVs (Fig. 2) and be able to accelerate the sampling process to capture rare dynamics events, such as the large-scale conformation changes.

Ever since the first algorithm of the metadynamics (Laio and Parrinello, 2002), many modified versions of metadynamics have been proposed, such as well-tempered (WT) metadynamics (Barducci *et al.*, 2008), the bias-exchange approach (Piana and Laio, 2007) and the parallel tempering (PT) metadynamics (Bussi *et al.*, 2006a). Besides, new CVs as reviewed in the reference (Sutto *et al.*, 2012), such as widely used path variables, principle component analysis (PCA) variables, alpha RMSD, beta RMSD, and contact map variables, have accelerating the sampling efficiency vastly.

For a general understand of the metadynamics, we take the well-tempered metadynamics (Barducci *et al.*, 2008) as an example, and briefly introduce the rationales behind. Supposing that the microscopic coordinate $\mathbf{R}$ at temperature T has a potential $U(\mathbf{R}, t)$, the ultimate goal of metadynamics is to obtain the FES from the unbiased probability distribution $P(s(\mathbf{R}))$ along the CV $s(\mathbf{R})$ by solving the following equation:

$$F(s) = - \frac{1}{\beta} \log P(s) \quad (15)$$

where the $\beta = \frac{1}{k_B T}$, k_B is the Boltzmann constant. For the unbiased, $P(s)$ we could have:

Fig. 2 A cartoon representation of metadynamics. During metadynamics simulations, gaussian shape biases are deposited along specific coordinates (or CVs).

$$P(R, t) = \frac{e^{-\beta U(R)}}{\int dR e^{-\beta U(R)}} \quad (16)$$

By adding a history-dependent bias potential as the following

$$V(s, t) = \Delta T \ln \left(1 + \frac{\omega N(s, t)}{\Delta T} \right) \quad (17)$$

where $N(s, t) = \int_0^t \delta_{s,s(t')} dt'$ is the histogram of the CV $s(\mathbf{R})$, ω is energy related term, ΔT is a temperature which we would explain in detail later. For this equation, $V(s, t)$ disfavors the frequently visited space in CV $s(\mathbf{R})$. The first order derivate of the $V(s, t)$ could be expressed as following:

$$\dot{V}(s, t) = \frac{\omega \Delta T \delta_{s,s(t)}}{\Delta T + \omega N(s, t)} = \omega e^{-\frac{V(s, t)}{\Delta T}} \delta_{s,s(t)} \quad (18)$$

Then we use τ_G to replace $\delta_{s,s(t)}$, and let $w = \omega e^{-\frac{V(s, t)}{\Delta T}} \tau_G$, where τ_G is the Gaussian height deposit time step. By incorporating the Eq. (18) into the standard metadynamics, where the height of Gaussian deposited is a constant, we could modulate the bias potential as a history dependent style.

As the time t flows, $\dot{V}(s, t)$ could be determined by $\frac{V(s, t)}{\Delta T}$, which indicates at position where $V(s, t)$ is large, the $\dot{V}(s, t)$ is close to zero to resemble a thermodynamic equilibrium. At this situation, one might get $P(s, t) ds \propto e^{-\frac{F(s) - V(s, t)}{T}} ds$, based on that, then one could have the following relationship between $\dot{V}(s, t)$ and $F(s)$:

$$\dot{V}(s, t) = \omega e^{-\frac{V(s, t)}{\Delta T}} P(s, t) = \omega e^{-\frac{V(s, t)}{\Delta T}} \frac{e^{-\frac{F(s) - V(s, t)}{T}}}{\int ds e^{-\frac{F(s) - V(s, t)}{T}}} \quad (19)$$

While the time $t \rightarrow \infty$,

$$V(s) = -\frac{\Delta T}{T + \Delta T} F(s) \quad (20)$$

If we go a step further, we could have $F(s) + V(s) = \frac{T}{T + \Delta T} F(s)$. Until now, we have established the relationship between $V(s, t)$ with $F(s)$ in a simpler way. Combining Eq. (19) with Eq. (20), we then can deduce the estimation of $F(s)$:

$$\tilde{F}(s, t) = -\frac{T + \Delta T}{\Delta T} V(s, t) = -(T + \Delta T) \ln \left(1 + \frac{\omega N(s, t)}{\Delta T} \right) \quad (21)$$

From Eq. (21), we could estimate the final FES by calculating the histogram $N(s, t)$ of CV $s(\mathbf{R})$. The modulation of the constant ΔT could define different behavior of the Gaussian deposit. For $\Delta T = 0$, the bias potential added in the system is always 0 along the simulation time t . Another limiting case, if $T \rightarrow \infty$, then $-\frac{T + \Delta T}{\Delta T} \rightarrow -1$, thus we could give the conclusion that $\tilde{F}(s, t) \approx -V(s, t)$, which is the case in the standard metadynamics where the bias potential energy, added in the system along the CVs space, has the same absolute value as the FES along the same CVs space. What's more, a finite value of ΔT , therefore restricts the system from exploring all the physical space and ensures a thermodynamic equilibrium at local minima in FES. Fine tuning of this ΔT could facilitate us to better explore the CVs space. By calculating the $V(s, t)$ in the following equation:

$$V(s, t) = w \sum_{t' = \tau_G, 2\tau_G, 3\tau_G, \dots} e^{\left(\frac{-s(\mathbf{R}) + s(R_G(t'))}{2\delta^2} \right)^2} \quad (22)$$

where w and δ have been defined already. Finally, we could recover the $\tilde{F}(s, t)$ from the biased probability distribution of $s(\mathbf{R})$.

In practice, we often use the following bias factor $\gamma = \frac{T + \Delta T}{T}$ to set up the ΔT . τ_G is the Gaussian deposition stride, and another input value ω in $w = \omega e^{-\frac{V(s, t)}{\Delta T}} \tau_G$, is the initial Gaussian height. And the δ is the width of the Gaussian for the CV $s(\mathbf{R})$.

Plumed (Bonomi et al., 2009) and METAGUI (Biamés et al., 2012) (a VMD plugin), are example softwares which make the simulation and the post-process of the data much more convenient. The usage and tutorials of the tool could be found here: see "Relevant Websites section".

Replica exchange MD (REMD)

Conventional MD simulation takes long time simulation to sample large conformational changes, or observe biological relevant behaviors. In most cases, simulation system would be trapped in local potential energy minima, which limit the sampling efficiency. To overcome the potential energy barriers and search for the global energy basins, REMD (sometimes also called generalized ensemble method), emerged as an efficient sampling technique (Sugita and Okamoto, 1999b; La Penna et al., 2004; Mitsutake et al., 2001; Tai, 2004). A lot of researches have demonstrated that the REMD method is much more efficient than the conventional MD (García and Sanbonmatsu, 2002; Sugita and Okamoto, 1999b).

In practice, M replicas in canonical ensemble are simulated with fixed distinct temperatures independently and spontaneously for some MD (or MC) steps, though the optimal number of steps between exchanges are controversial (Sindhikara et al., 2008; Cecchini et al., 2004; Zhang et al., 2005b). Then, the adjacent replicas (say m and $m + 1$) could exchange their configurations based

Fig. 3 A cartoon representation of REMD methods.

on the Metropolis criterion (Swendsen and Wang, 1987). Once the exchange occurs, replica m swamps the configuration with replica $m + 1$ and continues at the fixed temperature. Fig. 3 shows a sketch representation of the idea.

The idea was based on the hypothesis that at higher temperature, the potential energy of the simulation system is much higher and the system is much easier to escape the local energy minima to explore global energy minima. The potential energies of the parallel systems (replicas) in different simulating temperatures may overlap, thus the low energy conformations from high temperature replicas could be exchanged to lower temperature replicas and stabilized and sampled in lower temperature replicas. This way, in normal temperature range, the replicas could sample the structures with low potential energy, and the sampling efficiency therefore suppresses the conventional single trajectory MD simulation.

Here, we briefly illustrate the exchange method, the Metropolis scheme, used in REMD. The Metropolis criterion specifies that the exchange between neighboring replicas m and $m + 1$ at temperature T_m and T_{m+1} could take place with an acceptance probability P to ensure the detailed balance, $P = e^{(\beta_m - \beta_{m+1})(F_m - F_{m+1})}$, where F_m and F_{m+1} are the potential energies of replica m and replica $m + 1$. And $\beta_m = 1/(k_B T_m)$, where k_B is the Boltzmann's constant. To achieve acceptable exchange ratio, certain temperature intervals between replicas should be selected to ensure enough overlapping of the potential energies of neighboring replicas (Kone and Kofke, 2005; Sugita and Okamoto, 1999b).

The convergence problem is one of the major issues to achieve a statistical meaningful REMD simulation (Lin and Shell, 2009; Denschlag *et al.*, 2008; Okur *et al.*, 2007; Zhang *et al.*, 2005a). It has been widely discussed in many researches and reviews, therefore we are not going to elucidate it in detail here.

Hamiltonian REMD

The conventional REMD tends to sample low energy structure and then deposits it in the low temperature replicas, thus it is blind sampling and requires no prior knowledge of the simulation system. During REMD simulation, the number of required replicas to ensure enough potential energy overlapping between adjacent replicas is exponentially increased along with the system size, therefore relies on tremendous amount of computational power, and increases the difficulty of convergence, thus those limit the usage of REMD for huge simulation systems.

Instead of exchanging between different temperatures, Hamiltonian could also be exchanged between replicas if there are possible potential energies overlapping (Affentranger *et al.*, 2006; Fukunishi *et al.*, 2002; Curuksu and Zacharias, 2009). Hamiltonian REMD is quite similar to REMD, where each replica samples independently in different environments (temperature for REMD, Hamiltonian for Hamiltonian REMD respectively). The exchanges every N step in Hamiltonian REMD also obey the metropolitan rule.

For Hamiltonian REMD, the Hamiltonian of each replica is scaled by a factor λ . It has to be ensured that the first replica has a normal Hamiltonian, while other λ values increase or decrease sequentially. In the same time, the λ values should be set appropriately thus enough overlapping of potential energies between adjacent replicas must be retained. There are several ways to modulate the Hamiltonian of simulation systems, for example, reducing the atomic charges of a molecule, increasing intra-molecular repulsions (Mu, 2009), decreasing interatomic attractions, increasing molecular hydrophobic interactions, or modifying the atomic charges of atoms.

The combination of Hamiltonian simulation with REMD is proved to be a good practice. Using different Hamiltonian, we could actually bias the systems towards different directions. Hamiltonian REMD thus is not blindly sampling, nor the CV based sampling, but something in between.

Monte Carlo Simulation

The essence of Monte Carlo (MC) simulation lies on the "randomness". Multiple repeated random sampling using MC simulation could obtain statistical data for systems with multiple degrees of freedom. However, in general, in order to sample the configurational space of the system sufficiently, brute force MD method requires tons of millions of repeats to complete, therefore, analytic techniques must be used (Frenkel and Smit, 2001; Heermann, 1990).

Metropolis method was introduced to facilitate random sampling in MC simulation. In each step, a small random displacement Δ of a particle is tried. The displacement Δ is generated from a relative probability distribution proportional to the Boltzmann

factor $e^{-\beta U(o)}$, where β is $\frac{1}{k_B T}$. $U(o)$ is the potential of the system in previous step. This trial displacement is then assessed to accept or reject based on many rules, one of which is the Metropolis scheme, simple but applicable (Kalos and Whitlock, 2008).

To make it simpler, the system in previous state is called o (old), the system state after the displacement is denoted as n (new). The transition probability from o to n , therefore is determined here:

$$P(o \rightarrow n) = e^{-\beta[U(n) - U(o)]} \quad (23)$$

$U(n)$ and $U(o)$ are the potential energies of the old state and the new state. After the trial displacement, a random number r from the uniform distribution between 0 and 1 is generated and compared to $P(o \rightarrow n)$. The displacement would be accepted if $r < P(o \rightarrow n)$, otherwise, it would be rejected. This way, it is ensured that the acceptance probability from state o to n is equal to $P(o \rightarrow n)$.

The Metropolis scheme is efficient, but only thought to be ergodic for simple systems, therefore, the mixed schemes with efficient Metropolis scheme with other in principle ergodic scheme would achieve an statistical reliable simulation (Frenkel and Smit, 2001). In contrast to MD simulation, in general, MC simulation focuses on sampling, rather than time-dependent events, therefore it is not advisable to extract time dependent phenomena from the MC simulations.

Systems/Applications

Molecular dynamics have been widely adopted in molecular modeling of organic chemicals, short peptides (Woutersen *et al.*, 2002; Snow *et al.*, 2002; Marinelli *et al.*, 2009; Gnanakaran *et al.*, 2003; Blanco *et al.*, 1994; Ma and Nussinov, 2002), protein-protein interactions (Arkin *et al.*, 2014; Baaden and Marrink, 2013; Rajamani *et al.*, 2004), lipid-protein complexes (Shrivastava and Sansom, 2000; Im and Roux, 2002; Khalili-Araghi *et al.*, 2009; Gumbart *et al.*, 2005; Woutersen *et al.*, 2002; Snow *et al.*, 2002; Marinelli *et al.*, 2009; Gnanakaran *et al.*, 2003; Blanco *et al.*, 1994; Ma and Nussinov, 2002), even virus capsid (Freddolino *et al.*, 2006; Miao *et al.*, 2010). By harnessing the computation power from the supercomputing facilities, the physical properties of sub-micrometer particles could be revealed. Using MD simulations, as well as other simulation methods, stable conformations, the folding process, energy landscape, transitions between macro-states, enzyme catalytic mechanisms, ligand binding/association and aggregation states could be examined. Besides, MD simulations are also commonly used in computational drug discovery and design (Borhani and Shaw, 2012; De Vivo *et al.*, 2016; Durrant and McCammon, 2011).

For example, the enhanced sampling methods, umbrella sampling and metadynamics simulation could be applied to recover the free energy landscape of a macromolecule system along some specific collective variables, such as RMSD, PCA components, helical contents, angles, and other high dimensional coordinates. Bias potentials are deposited in simulations and the post-processing reweight techniques would then recover the true energy landscape of the simulation system along selected dimensions. The combination of metadynamics with REMD, or parallel exchanges between replicas biasing difference collective variables are proved to be more efficient and converges faster than the single-trajectory metadynamics simulations (Abrams and Bussi, 2013; Piana and Laio, 2007; Barducci *et al.*, 2011).

By incorporating multiple short MD simulations, Markov state model (HMM) could be applied to analyze the trajectories and compute the transition dynamics of proteins or protein-ligand systems between macro-states of the systems (Beauchamp *et al.*, 2012; McGibbon and Pande, 2013; Suárez *et al.*, 2016). Starting from different initial structures, it is expected that multiple short simulations starting in different directions are more powerful in conformational sampling than a single long trajectory. Combining the short simulations, several macro-states of the system could be identified using different methods, such as clustering and independent component analysis. The transition probabilities between the microstate then would be derived from the trajectories, and More importantly, the transition time scales could be estimated.

What's more, combining MD simulation with quantum calculation, more accurate enzyme activation mechanisms (van der Kamp and Mulholland, 2013; Hu *et al.*, 2011; Riccardi *et al.*, 2010; Senn and Thiel, 2007; Zhang *et al.*, 2000). The statistic properties could also be calculated and compared to experiments.

MD Simulation With Molecular Docking

Molecular docking is a simplified form of MD simulation. It can be used on intervals to replace lengthy segments of MD simulation trajectories, especially in cases where certain domains undergo large translations, rotations, and conformation changes. A typical example is biological interactions that include large protein folding, like capsid or vesicle formation. To be able to replace lengthy MD simulation intervals with docking, it is necessary to be able to perform "blind docking" of a protein (or a domain) to the whole surface of another protein. Some tools claim the ability to perform blind docking, for example QuickVina-W (111), PatchDock (222), BSP-SLIM (333) (Nafisa *et al.*, 2017; Schneidman-Duhovny *et al.*, 2005; Lee and Zhang, 2012).

Markov State Model (MSM)

The dynamics and kinetics properties are extremely valuable for a deep understanding of the structure-function relationships. MD simulation method has its innate advantage over current experimental techniques in exploring macromolecules kinetics and dynamics. By using MSM, or Hidden Markov State Model (HMM), the dynamics properties of proteins, as well as other

macromolecules, could be estimated with near to experiment accuracy (Beauchamp *et al.*, 2012; Suárez *et al.*, 2016; McGibbon and Pande, 2013; Noé *et al.*, 2009; McGibbon *et al.*, 2014; Husic and Pande, 2018).

Here we briefly explain the four general steps applied in most MSM studies for macromolecules dynamics and kinetics.

1. Extensive short MD simulations. The idea of constructing transitions between macro-states is based on such a hypothesis that we could adequately sample all the microstates, as well as their transitions. Therefore, in practice, other than a single long MD trajectory, multiple short MD simulations could be performed to sample as many intermediate states as possible (Noé *et al.*, 2009). Certain intermediate structures are selected as "seeding" initial structures for further high throughput short MD simulations, or adaptive sampling (Singhal and Pande, 2005; Pande *et al.*, 2010; Doerr and De Fabritiis, 2014; Doerr *et al.*, 2016).
2. Features dimension reduction. The features harnessed in previous step are then transformed into low dimensional vectors and clustering of the vectors could be applied to capture the microstates of the conformations. The coordinates of the trajectories are transformed into vector features. The features could be RMSD of a structure, dihedral angles of backbone atoms, distance between alpha-carbon atoms, or contacts between alpha-carbon atoms (Naritomi and Fuchigami, 2011; Pérez-Hernández *et al.*, 2013). Radius of gyrate, coordination number, PCA and time lagged independent component analysis (tICA) (Schwantes *et al.*, 2015; Noé and Clementi, 2015) are commonly applied in this dimension reduction step.
3. Microstates clustering. The distance matrices with clustering strategy is proved to be reliable for partitioning the phase space (Pande *et al.*, 2010; Chodera and Noé, 2014; McGibbon and Pande, 2013). The conformations from trajectories would be clustered, based on the low dimensional vectors calculated in step 2, to form microstates which could be rapidly interconverted between each other. Several commonly used clustering methods include K-mean-like clustering and hierarchical clustering. For an easy visualization of the MSM network, fewer macrostate are chosen, using the so-called "lumping" scheme using principal canonical correlation analysis (PCCA) or PCCA + methods.
4. MSM construction. Then using maximum likelihood method to estimate the transition rates between the states, and then construct the MSM, and estimate the kinetics of the MSM network (Weber, 2011; Röblitz and Weber, 2013).

Currently, there are majorly two tools, Pyemma (Scherer *et al.*, 2015) and MSMBuilder (Harrigan *et al.*, 2017), available for MSM or HMM construction. Their tutorials and manuals could be found here: see "Relevant Websites section" and see "Relevant Websites section".

MD Simulation With Machine Learning

The combination of machine learning and chemical informatics in drug discovery has been proved to be very successful for predicting ligand binding affinity (Ballester and Mitchell, 2010; Cheng *et al.*, 2012), drug toxicity (Walters and Murcko, 2002; Judson *et al.*, 2008), membrane permeability (Doniger *et al.*, 2002; Hou *et al.*, 2006; Walters and Murcko, 2002) and so on. In structural biology, machine learning models could advance the protein-protein binding interface prediction (Lise *et al.*, 2009), protein folding prediction, and protein structure prediction (Hua and Sun, 2001; Cai *et al.*, 2002; Heffernan *et al.*, 2015; Wang *et al.*, 2016).

Recently, machine learning algorithms have also been introduced into MD simulations for faster, more accurate sampling and predictions (Behler, 2016), for example, in metadynamics simulations. Proper CVs should be carefully chosen to achieve successful sampling. A recent work illustrates the probability of using neural network to reduce dimensions in tICA calculation and aiding the enhanced sampling (Sultan *et al.*, 2018). Or using machine learning algorithms to perform or instruct the way of bias quantum deposit to achieve high dimensional enhanced sampling (Galvelis and Sugita, 2017).

Quantum calculation based first-principles molecular dynamics (FPMD) are useful in understanding chemical processes, however, FPMD could only simulate up to hundreds of atoms within a very short simulation time to the limitations of computation power. There have been a lot of studies trying to adopt machine learning methods, such as neural network and Gaussian Processes, to predict the quantum level potential energy surface, thus further to obtain the atomic forces imposed in atoms (Behler and Parrinello, 2007; Bartók *et al.*, 2010; Botu and Ramprasad, 2015; Li *et al.*, 2015).

Illustrative Example(s) or Case Studies

Here, we use two examples to illustrate the applications of molecular dynamics and simulations in biophysics field.

Conformations and Energy Landscapes of *apo*-form PR LBD

Progesterone receptor (PR) is a member of the nuclear receptor (NR) family. PR is the natural receptor of the important female hormone progesterone, which affects every aspect in female development, maintenance and reproductive. The ligand binding domain (LBD) of PR, shares a similar sandwich like folding as other LBDs in NR. Though, several crystal structures of ligand bound (and co-peptides bound) PR LBD have been deposited in PDB databank, the *apo*-form (non-ligand bound state) PR LBD conformation, which is valuable for structural based virtual screening to identify druggable ligands, is still void. Combining conventional MD, umbrella sampling (Wang *et al.*, 2014), and metadynamics (Laio and Parrinello, 2002; Laio and Gervasio, 2008), the *apo*-form PR LBD has been thoroughly examined using the popular amber99SB-ildn force in explicit water environment (Zheng *et al.*, 2016). Multiple analysis methods, such as dihedral PCA, correlation analysis, reweighting, were applied. The free

energy landscape of the *apo*-form PR LBD was constructed, indicating the agonistic conformation of *apo*-form PR LBD is a meta-stable state, though not the most stable one. Several stable conformations were identified and are useful for further virtual screening study. E723, N719 and R899 are identified as key residues for conformation dynamics for helix 3 and helix 12., and metadynamics (Laio and Parrinello, 2002; Laio and Gervasio, 2008), the *apo*-form PR LBD has been thoroughly examined using the popular amber99SB-ildn force in explicit water environment (Zheng *et al.*, 2016). Multiple analysis methods, such as dihedral PCA (Mu *et al.*, 2005), correlation analysis (Göbel *et al.*, 1994), reweighting (Tiwarý and Parrinello, 2014), were applied. The free energy landscape of the *apo*-form PR LBD was constructed, indicating the agonistic conformation of *apo*-form PR LBD is a meta-stable state, though not the most stable one. Several stable conformations were identified and are useful for further virtual screening study. E723, N719 and R899 are identified as key residues for conformation dynamics for helix 3 and helix 12.

Understanding SAC6 Inter-Domain Peptides Flexibility

Another example is the dynamics study of a short peptide from yeast SAC6 inter-domain loop region (Miao *et al.*, 2016). SAC6 composed by two domains, is actin binding protein upon phosphorylation. T103 is a high potent phosphorylation site. However, why phosphorylated SAC6 has higher actin binding activity is poorly understood. We firstly hypothesized that the inter-domain peptides where T103 resides, behave differently with or without phosphorylation.

By comparing the dynamics property of two simulation systems (T103 phosphorylated and non-phosphorylated respectively), it turns out that phosphorylated T103 could restrict the peptide flexibility through electrostatic interactions with lysine and arginine residues, meanwhile phosphorylated T103 could form a hydrogen bond with G109. This hydrogen bond maintains the turn structure around G109. Free energy landscape and clustering analysis both suggest that phosphorylation at T103 stabilizes the peptides, thus facilitates the actin binding with the actin binding domains in SAC6.

Future Directions

The future of molecular simulations moves towards a more accurate, large system scale, longer simulation time scale. The polarized force field, though computational intensive, is supposed to be more precise than conventional single charge force field. The combination of quantum simulation, MMQM simulations are powerful for enzyme catalytic center accurate enough comparing to experimental results.

The fast advancement of supercomputer facilities, as well as the adaption from CPU simulations towards GPU simulations, vastly increases our confidences of future of molecular simulation. In another hand, less accurate models, such as coarse graining methods, have drawn great attention due to their ability of decreasing computational power and increasing simulation time scale.

GPU Accelerated MD Simulations

GPUs have been gradually adopted in many analytic fields, such as machine learning and simulations. Recent years, many popular simulation packages, such as Amber, Gromacs, and NAMD, have all embraced the powerful GPUs based using CUDA library. Other

Fig. 4 GPU benchmark for cellulose system MD simulations with Amber 16. a) the simulation box of cellulose in explicit waters, with 408,609 atoms in total. b), performance of different GPUs and different CPU cores. The CPUs used in this benchmark are Intel Xeon E5-2683 V4 and E2650 V3.

new generation of simulation packages, such as openmm, htmd, and acemd all support GPU calculations. Gromacs, starting from version 4.5, implemented GPU calculations and combined them with CPUs to accelerate MD simulations (Abraham *et al.*, 2015; van der Spoel and Hess, 2011). Later in version 4.6 and higher, native GPU support has been developed to handle the most computational intensive non-bonded interactions based on CUDA library, while the PME electrostatics, bonded interactions and input-output are subjected to CPUs. Whereas, in Amber, GPUs handle nearly all calculations, such as energy evaluation, bonded and non-bonded forces.

Taking cellulose-water system (~41,000 atoms) as a benchmark using Amber 16 for *NPT* MD simulations, mid-end GPU cards (GTX 1080 and 1080Ti) show rather surprising performance comparing to high-end GPUs, such as Tesla P100, Tesla K40 and K80, as shown in Fig. 4. Given that the prices of the mid-end Nvidia GPU cards are relatively cheap (see “Relevant Websites section”), these data thus indicate that GPUs outperform CPUs, and could be adopted for efficient MD simulations with an affordable budget.

Coarse Graining

Current all-atom molecular modeling techniques enable biological systems description with details limited to simulation times and system sizes less than 1000 ns and 100 nm respectively. Coarse Graining is developed for bridging the “time-scale” and “length-scale” gaps between computational and experimental methods. The general contract of all CG methods is representing a system by a reduced number of degrees of freedom (DOFs) and fine interaction details, by mapping from atomically detailed configuration (fine grains) into a CG configuration called super atom (coarse grain) (Zhang *et al.*, 2008). That reduces the system size about *ten* folds and allows time steps up to 25–50 fs (Shih *et al.*, 2006). This way, the simulation would go faster and require less computational resources than the all-atom representation while achieving an increase of orders of magnitude in the simulated time and length scales.

Defining a coarse grained system needs three components: 1) a method to map a set of fine grains to a coarse grain, 2) a method to define the location of the center of the newly introduced coarse grain, and 3) a method to derive a suitable force field for the system. The mapping process depends on the size and complexity of the biomolecules. Small and low details molecules mapping is straightforward while the mapping process of large and complex molecules is a challenging one.

Although coarse graining is not a new concept, it is expected to take bigger rule in the near future, as the direction would be towards simulating systems on larger time scale and size scale.

The *Implicit hydrogen* model (AKA *united atom*) is an old and simple form of coarse graining, where nonpolar hydrogens are omitted and implicitly included in their connected carbon atoms with reduced number of interaction sites to around half. The resulting interaction sites for CH₂, CH₃, and CH₄ are usually parametrized Lennard-Jones potentials.

There are two general CG approaches: the residue-based CG (Shih *et al.*, 2007), and the shape-based CG (Arhipov *et al.*, 2008). Zhang *et al.* (2008) designed a method called “essential dynamics coarse-graining (ED-CG)” to define CG sites from protein primary sequence that reflect the essential dynamics characterized by PCA of an atomistic trajectory.

Multiscale coarse-graining (MC-CG)

The multiscale coarse-graining method (MS-CG, aka “force matching”) is a method of decreasing the computational load of simulating a system by “optimizing a CG potential to reproduce many-body potentials of mean force (PMF) calculated from atomistic configurations” initially for non-bonded potentials and then for bonded interactions (Lu *et al.*, 2013).

Instead of the commonly used two-body approximation, Larini *et al.* (2010) in 2010 proved that using explicit three-body potentials is superior to the two-body approximation.

LY Lu and G. Voth in 2009 implemented B-spline basis function in the MS-CG method. Which shows dramatic reduction of memory requirements and increase in computational efficiency of the MS-CG calculation. Their work showed that the MS-CG force field can approximate the many-body PMF in the coarse-grained coordinates (Lu and Voth, 2009). Then in 2011, they showed that MS-CG method can also be used to analyze the CG interactions from atomistic MD trajectories via PMF calculations and its performance is comparable to various free energy computation methods (Lu and Voth, 2011). The distribution function defined in the coarse-grained potential could be reproduced by iteratively applying the MS-CG algorithm (Lu *et al.*, 2013). It has been proven that both of the two common methods “postprocessing method” and “fixed part method” (Das and Andersen, 2009; Noid *et al.*, 2008) can similarly make MS-CG potentials which are limited in accuracy only by the incompleteness of the basis set usable (Das *et al.*, 2012).

Finally, it is worth noting that it is necessary to intervene in the variational calculation in some way, in case we need to produce accurate MS-CG potential in both high and average potential energy regions (Das *et al.*, 2012).

Multilevel coarse graining

Multilevel coarse graining is the future of coarse graining. This direction is not yet well defined. Generally, it is expected that future simulation packages can simulate systems in a heterogeneous way. Fine details can be simulated using a fine detailed model on minor steps, while coarser details can be simulated using less detailed models and over bigger time steps. One way to achieve this goal can be including the defined coarse grains into *further coarser* grains in a hierarchal way. Examples of coarse details may include diffusion and movement in the solvent, which can be simulated using models like Brownian dynamics, ignoring the detailed atom-atom interactions, but rather modeling their overall effect as a continuum.

Force fields used in CG MD simulation

Pair-potentials vs. many-body potentials

One essential requirement for any simulation package is the definition of a potential function, which describes how the simulated particles in the system would interact. Such function is known as the Force Field. Force Fields are usually empirical, and they usually employ preset bonding arrangements, which makes them capable of modeling structural and conformational changes but not chemical reactions (bond breaking and reformation) explicitly.

Force field potential function can be either *pair-potential* function, where the force is calculated as a sum of pairwise interactions between particles (e.g., Lennard-Jones potential of Van der Waals force and Born (ionic) model of the ionic lattice), or *many-body potentials*, where three or more particles interact with each other. Examples of the later are Tersoff potential (Tersoff, 1989), embedded-atom method (EAM) (Daw *et al.*, 1993), and Tight-Binding Second Moment Approximation (TBSMA) (Cleri and Rosato, 1993) potentials.

Static partial charges vs. polarizable potentials

Most force fields (especially experimental Force fields) model the effect of polarizability as static partial charges. While new techniques model polarizability as fluctuating charges, electronic structural theory, induced dipole, distributed multipoles, point charges, Bond Polarization Theory (BPT). Increased accuracy was achieved using fluctuating charges in water molecules (Lamoureux *et al.*, 2006) and with some promising results for proteins (Patel *et al.*, 2004).

Coarse-grained force fields

Coarse-Grained Force Fields can be based on generic atom types (e.g., MARTINI Force Field), or on secondary structure (e.g., VAMM).

MARTINI (Marrink *et al.*, 2004, 2007) is a very common Coarse Grained Force Field, based on having four categories of particles/beads (Q (charged), P (polar), N (nonpolar) and C (apolar)). They are then split in 4 or 5 levels, summing up to a total of 20 bead types. It has parameters for lipids, proteins, carbohydrates, DNA, RNA, and molecule types available for download on their website.

On the other hand, VAMM (Virtual Atom Molecular Mechanics) (Korkut and Hendrickson, 2009) is a “knowledge based” force field developed to model large scale conformational transitions based on the virtual interactions of C-alpha atoms and on secondary structure and residue specific contact features.

Finite Element Method

Finite element method is a common method of numerical solution of complex problems including force and heat acting on irregular structures. It is mostly used for structural mechanics applications. In this method, the system is modelled as a set of finite elements of appropriate properties (e.g., stiffness, toughness, etc.), interconnected at points called nodes.

Although the method is famous for use in civil engineering applications to solve displacement versus boundary and load conditions, it can be applied on smaller scale objects with high efficiency in terms of speed and accuracy. For instance, in 1999 O'Brien *et al.* simulated different fractured objects of different toughness property after collisions, using continuously remeshing technique and it was comparative to experimental results (O'Brien and Hodgins, 1999).

Even on the molecular levels there have been promising trails to combine FEM and MD simulation to model silicon (Izumi *et al.*, 1999) and LASER induced pressure wave propagation (Smirnova *et al.*, 1999). In 2013, Lee *et al.* published a multiscale modeling technique for bridging molecular dynamics with finite element method, based on weighted average momentum principle. Their work was applied on 2-D problems, but to the best of our knowledge, no 3D applications are available so far (Lee and Basaran, 2013).

Closing Remarks

Along with the vast increasing in supercomputing power, MD simulations, as well as other simulation variants, are gradually adopted to explore more complex biological systems, from electron level to molecule level, and evolve to achieve free energy surface construction and states-transition with affordable time and resources. In this chapter, we went through the basics of MD simulation, and then explained the advanced sampling methods. Besides, we also illustrated some applications in alignment with MD simulation in biophysical and drug design field, and examples of applying MD simulation to address biological systems have been presented. Lastly, we discussed possible future developments and directions of MD and simulations. This review thus serves as a general introduction to MD simulation and its applications.

Biographical Sketch

Zheng Liangzhen is a PhD candidate in School of Biological Sciences, Nanyang Technological University, Singapore since 2014. He obtained his bachelor's degree in biological sciences from College of Life Science, Wuhan University, in 2010. His current interests are protein dynamics, protein-nucleic acid complex dynamics, and machine learning aided drug discovery.

Amr Alhossary received his M.B.B.S. from School of Medicine, Cairo University in 2003, then his Graduate diploma and M.Sc. in Bioinformatics from Faculty of Computers and Information, Helwan University in 2008 and 2012 respectively. He is currently a PhD candidate in School of Computer Science and Engineering, Nanyang Technological University, Singapore. His research interests include Structural Computational Biology, Molecular Docking, and Drug Design.

Kwoh Chee Keong is currently in the School of Computer Science and Engineering since 1993. He is currently the Assistant Chair (Graduate Studies). He received his Bachelor degree in Electrical Engineering (1st Class) and Master in Industrial System Engineering from the National University of Singapore in 1987 and 1991 respectively. He received his Ph.D. degrees from the Imperial College, University of London in 1995. He is often invited for conferences and journals, including GIW, IEEE BIBM, RECOMB, PRIB etc. He is a member of The Institution of Engineers Singapore, Association for Medical and Bio-Informatics, Imperial College Alumni Association of Singapore (ICAAS). He was conferred the Public Service Medal, the President of Singapore in 2008. His research interests include Data Mining and Soft Computing and Graph-Based inference; applications areas include Bioinformatics and Biomedical Engineering.

Mu Yuguang received his B.Sc. in Physics, M.S. in Quantum Chemistry, and Ph.D. Physics from Shandong University, China in 1991, 1994, and 1997 respectively. He worked as a Lecturer in Department of photoelectronics, Shandong University before moving to Germany in 2009 to work as a research fellow in Fraunhofer Institute of Integrated Systems and Device Technology (IISB) then Institute of Theoretical Chemistry Frankfurt. He has been in School of Biological Sciences, NTU, since 2003, as a Lee Kuan Yew Fellowship Scholar then Assistant and associate professor until now. His research interests include MD simulation method and data-analysis method development; protein folding and unfolding; RNA dynamics; DNA dynamics; DNA-protein; and DNA-counterions interaction study.

Nucleic-Acid Structure Database

Introduction

Nucleic acids have a significant role in the development of living systems. They contain wholesome interesting information related to the molecular biologists. They are extensively studied both for biological applications and for various databases. The nucleic acids that consist of RNAs are considered as the main target for several specialized databases. The sequence of nucleic acids consists of numerous control regions such as promoters, splice junctions, origins of replication, etc. The 3D structure of nucleic acid can be well understood by investigating the different types of nucleic acid functions such as nucleic acid–protein interactions, functional RNAs, etc. Several databases have been developed till date based on the nucleic acid sequence apart from some that have been developed from the structures storing information related to the secondary and tertiary structures.

Background

The molecules of nucleic acids allow to transfer the genetic information from one generation to the next generation. The nucleic acids are abundantly found in the nucleus of the cell. These nucleic acids are long polymers that are built up of several units of nucleotide monomers such as C (cytosine), A (adenine), G (guanine), T (thymine), and U (uracil). There are two types of nucleic acids, that is, deoxyribonucleic acid (DNA) and ribonucleic acid (RNA). The structure of DNA is coiled together by both the strands of nucleotide polymer chains (C, A, G, T) to form a double-helical pattern. The double-helical pattern of DNA is further stabilized by the formation of hydrogen bonds between the bases of nucleotides characterized on the chemical affinity. These chemical affinities defined by the nucleotides signify adenine with thymine and cytosine with guanine. On the other hand, RNA consists of a single strand of polymer with nucleotides C, A, G, and U. The structure of RNA has the ability to fold itself and obtain a secondary structure that is important for carrying out the various biological processes. Among both the nucleic acids, the DNA molecule stores the genetic information of the cell and carries that information from parent to offspring. In case of some viruses, the RNA stores the genetic information that is needed for the cell. However the information that is related to the life cycle of the cell and also its activities are stored in the DNA. The molecule of RNA is being built up when the complex biochemical decodification machinery present in the cell reacts on the DNA molecule to acquire information required for a specific function. The RNA molecule is the primary constituent for the process of protein synthesis. It is also accountable for transmitting the genetic information that is encoded within the DNA to construct a specific protein that is required for a specific function in a specific procedure. There exist three main types of RNA, which are *mRNA*, *tRNA*, and *rRNA*. *mRNA* is messenger RNA, which initiates the information required for building the protein molecule from the nucleus to the cytoplasm. *tRNA*, also known as transfer RNA, on the other hand transports the amino acids to the ribosomes for making the proteins. The *rRNA*, or ribosomal RNA, is connected with a variety of proteins that form the ribosomes. The complex structures thus formed catalyze the association of amino acids to form protein chains by moving along with the *mRNA* molecule. Also they are involved in the process of protein synthesis by binding to the *tRNAs* and other accessory molecules. Apart from these, there also exists regulatory RNA, which has the ability to regulate the gene expression from the various mechanisms such as blocking or interference (Alberts *et al.*, 2002; Bailey, 2017; Chen *et al.*, 1995; Darnell, 1985; Dickerson *et al.*, 1982; Felsenfeld, 1985; Katsuyuki *et al.*, 2016; Krieger *et al.*, 2004; Mirkin, 2001; Travers and Muskhelishvili, 2015; Watson and Crick, 1953; Weinberg, 1985).

The proteins interact with the nucleic acids, mainly DNA and RNA, by means of similar physical forces that consist of dipolar interactions (hydrogen bonding, H-bonds), electrostatic interactions (salt-bridges), effect of entropy (hydrophobic interactions), and also forces of dispersion (base stacking). These physical forces, which are acted upon by the interactions, help in varying degrees of binding of the proteins in a sequence-specific (*tight*) or non-sequence-specific (*loose*) orientation. Apart from that, the affinity and specificity of a particular protein–nucleic acid interaction is increased via the protein oligomerization or multiprotein complex formation. The secondary and tertiary structures that are formed from the nucleic acid sequences give an additional mechanism from which the proteins recognize themselves and then bind to the specific nucleic acid sequences. The DNA is a linear macromolecule that is found in most of the cells of living beings. Unlike proteins, it is made up of four diverse building blocks known as *nucleotides*. These nucleotides are made up of a base (purine or pyrimidine group) and a phosphate group (2'-deoxyribosyl-tri-phosphate). The bases present in the nucleotides are of four types. They are adenine and guanine present in *purine* and thymine and cytosine present in *pyrimidine*. The sugar present in the DNA is the 2'-deoxy ribose that is phosphorylated at position 5' of the hydroxyl group. The free nucleotide radical consists of any of one, two, or three phosphates that represent mono-, di-, or triphosphate, which are better known as *dATP*, *dGTP*, *dTTP*, and *dCTP*. These nucleotides are however linked covalently to the DNA via 5'-phosphate to 3'-hydroxyl of the subsequent nucleotide. The single strands of DNA are not stable, although they remain connected with another strand in order to form a double-helical structure such that both strands interlink around each other. The four bases situated at the center of the helix are H-bonded to one another in a very precise manner. The specific way that

the bases point towards the center of the helix and H-bond is as follows: G with C (3 H-bonds) and A with T (2 H-bonds). The linear geometry and rigidity associated with the H-bonds restricts the formation of *base pairs* (bp). The helical axis and the plane of the base pair are perpendicular to one another.

The B-DNA is the right-handed physiological form of double-helical DNA structure which was described by Watson and Crick in the year 1953. It is an antiparallel double-helical structure with a diameter of 2 nm. The B-DNA consists of 10 bp per turn, 36° per bp twist, 3.4 Å per base, 34 Å pitch, 2 nm diameter. These characteristics describe B-DNA as an idealized helical structure. The actual DNA conformation deviates from the B-form DNA conformation in both a sequence dependent manner and DNA-binding interaction protein.

The A-form of the DNA is a wider and flatter helical conformer with the base pair plane tilted to the helical axis. The helix of A-DNA possess the major and minor groove that consists of the respective parameters such as 11 bp per turn, 33° per turn twist, 0.26 nm per base, 2.8 nm pitch, 2.6 nm diameter, the base plane tilting to the helical axis with 20°.

Another form of DNA is the Z-DNA, which is a left-handed conformation consisting of the subsequent structural parameters, which are 12 bp per turn, 0.37 nm per base, 1.8 nm diameter, a tilt base of 7°, 4.5 nm pitch.

RNA is another nucleic acid, which is similar to DNA and is built up from four different building blocks that are the *ribonucleotides*. In case of RNA, thymine is modified such that it lacks a methyl group and results in the formation of uracil in the base-pairing mechanism. The ribose sugar present in the RNA comes along with a hydroxylated form. The presence of uracil instead of thymine and 2'-OH in the ribose sugar are the main chemical differences between the two nucleic acids, DNA and RNA. RNA is basically a single stranded helical structure. But both RNA and DNA form bp that result in the formation of a heteromeric double-helical secondary structure consisting of a single DNA and RNA strand. This process of annealing of RNA strand to the complementary DNA strand is known as the *hybridization process*. And this process however plays a significant role in the transcription and translation mechanism of the genetic sequences into protein sequences. As the RNA forms a short double strand structure on itself, hence it is known as the stem and loop structure. The double-helical structures DNA/RNA and RNA/RNA form an A-DNA-like conformation, better known as A-RNA or RNA-II. This helix consists of the following parameters: 11 bp per turn, 3.0 nm pitch (30 Å). In the RNA conformation, three major types exist, which are *messenger RNA (mRNA)*, *transfer RNA (tRNA)*, and *ribosomal RNA (rRNA)* (Alberts *et al.*, 2002; Bailey, 2017; Bansal, 2003; Chen *et al.*, 1995; Churchill, 1996; Darnell, 1985; Dickerson *et al.*, 1982; Felsenfeld, 1985; Katsuyuki *et al.*, 2016; Krieger *et al.*, 2004; Mirkin, 2001; Travers and Muskhelishvili, 2015; Watson and Crick, 1953; Weinberg, 1985).

The binding function of DNA or RNA is restricted in the distinct conserved domains that are within the tertiary structure. The affinity and specificity can be increased by binding the single protein with multiple nucleic acid binding domains for a specific target nucleic acid sequence. This can however lead to the development of a hierarchy of interactions as the proteins bind directly or indirectly to the nucleic acids via the other bound proteins. However we can gain a significant binding affinity for the protein and nucleic acids complex by understanding the strength of interactions influencing the approaches for the complex assembly. Among these interactions, some are recognized as transient, which need stabilization through chemical cross-linking prior to isolation of the complexes. Hence by studying the protein–nucleic acid interactions, the identification of protein in the complexes can be known and also the structure that is required to assemble these complexes is vital to understanding the role these complexes play in regulating cellular processes (Govil *et al.*, 1985; Luger and Phillips, 2010; Park *et al.*, 2014; Sathyapriya *et al.*, 2008; Siggers and Gordan, 2014; Valuchova *et al.*, 2016).

It has been observed that small, cationic, and planar molecules interpolate between the various bp whereas the large nonpolar molecules interact by the mechanism of groove binding. Various molecules for in vitro and in vivo activities have been tested and also some molecules from them have entered clinical trials. Hence various parameters that contain the experimental dataset required for drug-nucleic acid interactions have been established. These datasets contain the various types of ligands and binding parameters for their interaction with the associated nucleic acid. Although it becomes a challenging task to gather the whole information specifically for the ligand and its targets. However, by understanding the various interactions improvement in the projects of drug discovery can be achieved. Hence it is essential to combine those experimental data and information at a particular platform.

Nucleic Acid Database

NDB History, Sources and Number of NDB Data

The Nucleic Acid Database (NDB) was the first database for nucleic acid structures (Coimbatore Narayanan *et al.*, 2014), which was designed in the early 1990s and is considered as the main reference in the field of nucleic acids. The newly designed database (see “Relevant Websites section”), is a web portal that can provide access to various information related to 3D nucleic acid structures and their complexes. Apart from the contents of primary data, NDB also contains some derived geometric data, classification of structure and motifs, standards for describing nucleic acid features, and also tools and software for analysis of nucleic acids. In this review, we describe the recently redesigned NDB website with some special features related to new RNA-derived data and annotations and their implementation and integration into the search capabilities. This NDB database was founded in 1991 to assemble and distribute structural information about nucleic acids (Berman *et al.*, 1992). It contains annotations that are specific to the structure of nucleic acid and function and tools that allow users to search, download, analyze, and to learn more about nucleic acids apart from the contents available in PDB (Berman *et al.*, 2003). Thus, this database is a value-added one that provides services that are specific to the nucleic acid community. The main importance of NDB on its discovery was to focus on the DNA structural biology. However various tools and annotations have been developed that can address the various characteristics of these molecules as more RNA structures have been determined. It serves as a central medium for the nucleic acid

structural information and annotations. NDB at present consists of more than 8000 experimental structures for DNA and RNA molecules that are acquired and curated from the Protein Data Bank (PDB). The structures available in the NDB are annotated with various information that are unique to the nucleic acids but are almost not available from the original entry of PDB. The structures are further analyzed by means of computation of structural geometries and thereby classification was done by searching the sequence, structure levels, and secondary structure by incorporating the PDB entries to the NDB. By using the various tools that are available at the NDB server linked to the other resources, the specific analyses and online visualization in 2D and 3D can be carried out by the users. Apart from that, various new tools were developed in 2014 that are required to analyze the RNA sequences, DNA molecules, aligning RNA and DNA molecules, calculating and visualizing RNA structural geometries and base-pairing patterns that are comparatively more complex and diverse than DNA. This server also includes various statistics related to ideal geometries that are well suited for sugars, bases, and also for various hydrogen bonding pairing patterns that consist of a new catalog of base-pairing in RNA, an educational section, and software for further offline analyses.

NDB Entry Format

The main content of NDB is the primary structure information that is related to the nucleic acids that are acquired from the PDB and also from classification and derived data. The primary data present in the NDB that is obtained from PDB consists of experimental files, identifiers, structural descriptions, citations, crystal data, coordinate information, and various details related to the crystallization, data collection, and structure refinement. NDB also contains ERFs (external reference files), which mainly consist of nucleic acid classifications, calculated derived data, and additional derived data on RNA structural features. The web interface provides search, reporting, and also download functionalities. The results of these searches are returned as either group of structures or individual structures based on the query. These search results are related to a number of reporting features that include predefined feature reports, navigation to individual structure summary reports that further permit primary data files, derived data, and molecular images download. There are about three search options that are present from the secondary persistent header, that is, *ID search*, *search*, and *advanced search*. These search options can however be accessed in the *Search Structures*, a section available on the homepage.

The asymmetric unit's atomic coordinates and the biological assemblies are accessible from the *Downloads* section obtained from the corresponding NDB structure summary report, which is available both in *PDB* as well as *mmCIF* formats. This *mmCIF* format contains the structure factor data whereas the NMR restraint information is available in deposited program format. During the database update, the files are updated weekly and are downloadable from the NDB ftp server at website provided in "Relevant Websites section".

From the advanced search query, the featured reports for any result set are available. The predefined set of reports is such that it contains *NDB status*, *cell dimensions*, *citation*, *refinement data*, *backbone torsion*, *base pair and base step parameters*, *descriptor*, *sequence*, and *RNA motifs*. The report containing NDB status consists of parameters such as *NDB and PDB IDs*, *structure title*, *authors*, *deposition*, and *release dates* is the default report for any advanced search query.

The structures available in the NDB database possess their own personal summary page that is mostly appropriate to that particular structure. There are about four sections of data in the structure summary page, including (a) *primary structure information*, (b) *downloads*, (c) *derived structural data*, and (d) *images*. The primary structure information, which is the main division, encompasses the entry title, sequence, citation, experimental details, refinement information, and various structural descriptions. In the *Download Data* section, the details of the atomic coordinates, structure factors, and NMR restraint information are present. An RNA View Image is provided for the entries of RNA that represents 2D base pairing. Under the *More Images* link, various images are available including options such as *biological assemblies*, *crystal packing*, and *ensemble images*. Also in the *Structural Features* option, more advanced RNA-containing structures are now available. The motif for the base pair signature is provided that is available as the common name of the motif.

The various annotations used in nucleic acids are nucleic acid type and conformation, secondary structure, and description. Also information pertaining to the drug binding mode and bound proteins are also available. A schematic representation is shown that involves the various steps involved in the extraction and monitoring of data from the NDB (**Fig. 1**). A schematic representation of the NDB is depicted in **Fig. 1**.

The resources available for NDB can be retrieved via two constant headers that are available on top page of the website. There are six tabs that are contained in the first constant header. They are: *About NDB*, *Standards*, *Education*, *Tools*, *Software*, and *Download*. Introduction to nucleic acids; definitions of terms used in the website; nucleic acid-related features from PDB-101, an educational component of RCSB PDB (Rose *et al.*, 2013), and links to other educational activities and sites. The software is downloadable includes geometric and symbolic 3D motif search (*FR3D*) (Sarver *et al.*, 2008), visualization of secondary structure (*RNA View*) (Yang *et al.*, 2003), and visualization of 3D structures (*3DNA*) (Lu and Olson, 2003). There are various links to the software packages that include various software for statistical folding of nucleic acids and studies of regulatory RNAs (*Sfold*; see "Relevant Websites section") (Ding and Lawrence, 2003; Ding *et al.*, 2005), a visualization applet for RNA (*VARNA*) (Darty *et al.*, 2009) and the *UNAFold* web server (Markham and Zuker, 2005, 2008).

A representation of the structural summary report for the NDB is clearly shown that represents the various parameters and information obtained from the protein (**Fig. 2**). From the schematic representation, a snapshot for the reported data summary of the information related to ribozymes from the NDB can be obtained.

The information illustrated in the NDB has a good connection with the information related to the PDB. The summary report obtained from the PDB that is retained in the NDB is summarized in **Table 1**. From the table, we can observe the association between the NDB and PDB in terms of their contents and other specifiers.

Fig. 1 A database curator workflow for the various steps involved in the extraction and monitoring of data obtained from the NAD. Understanding bioinformatics, Marketa Zvelebil & Jeremy O. Baum.

NDB User Interface

Both the primary and derived data classification is obtained in the NDB. The derived and calculated data based on the structural features of RNA from the manually annotated nucleic acid classification are separately managed from the entries of primary structure. The data thus recorded and stored are kept as external reference files (ERFs). The respective PDB structures contain the primary data entries including the experimental files, structural descriptions, citations, crystal data, identifiers, coordinate information, details regarding crystallization, data collection, and structure refinement. The coordinate data that are stored in the searchable database store the various derived structural features such as bond distances, angles, torsions, and base morphology (Lu and Olson, 2003, 2008). The information related to the RNA structural features including pair-wise nucleotide interactions for each RNA structure, equivalence classes, and NR sets of RNA structure files and RNA 3D motifs extracted from structures were recently reported.

NDB Applications

For RNA base-pairing and base stacking interactions the *FR3D* server (Sarver *et al.*, 2008) is used to annotate the pair-wise interactions between RNA nucleotides, and is described in (Zirbel *et al.*, 2009) for base phosphate interactions. The basis for RNA Base Triple Atlas and RNA 3D Motif Atlas are formed from these annotations. Also statistics about pair-wise interaction frequency are provided. For modelers and computational scientists who are keen to determine the characteristics of structured RNAs, these data can be a useful target. Reports suggest that the entries of RNA are clumped into 'equivalence classes' of structures that share the same, or nearly the same, sequence and geometry (Leontis and Zirbel, 2012). For every week the equivalence classes are computed such that the 3D structure databases are reflected with new additions. The same equivalence class contains different structures of the same RNA from the same organism whereas difference class contains the homologous RNAs structures from different organisms.

Other Databases

Apart from NDB, there also exist other databases that are unique for RNA and that combine data from the other sources including NDB and also from directed PDB sites. These however supply an elaborated annotation that is combined with the sequence based predictions in most of the cases (Appasamy *et al.*, 2016; Chojnowski *et al.*, 2014; Firdaus-Raih *et al.*, 2014; Popenda *et al.*, 2010; Zirbel *et al.*, 2015). The majority of the servers however permit secondary structures and RNA sequences searches. They also help in analyzing and searching from the uploaded PDB file the likely coordinates of RNA. These findings depend on the geometries but they are not sustained presently by NDB. RNA 3D hub is another useful database related to the structure of RNA that gives details about the various information associated with the precomputed structural analyses part of RNA molecules available at NDB (Zirbel *et al.*, 2015).

Databases such as NDB, G4LDB, SMMRNA, etc., have been provided by various groups earlier. These databases are dedicated particular type of nucleic acid or its special structure. Databases such as NDB consist of the various information related to three-dimensional structures of nucleic acids and their complexes.

Fig. 2 A reported summary of the particular ribozyme that depicts the headers of gray and red color with the individual sections: (a) Primary structural information, (b) atomic coordinate and experimental file download, (c) derived structural data, (d) images, and (e) for RNA structures an additional RNA view image. Understanding bioinformatics, Marketa Zvelebil & Jeremy O. Baum.

The G4LDB database (G4LDB, see “Relevant Websites section”) is related to the G-quadruplex ligands with the docking tool. This database gives information about the unique collection of the reported G-quadruplex ligands associated with the streamline ligand/drug discovery targeting G-quadruplexes. The G-quadruplexes are those nucleic acid sequences that are guanine-rich found in the human telomeres and the promoter region of the gene. This database at present consists of more than 800 G-quadruplex ligands with 4000 activity records, which is the most extensive collection to our knowledge. It also provides a user-friendly interface that necessitates various data inquired from researchers (Li *et al.*, 2012).

The SMMRNA database relates to the RNA structure and its complexes with small molecules (Li, *et al.*, 2013; Mehta *et al.*, 2014). This is an interactive database that is available at website provided in “Relevant Websites section” and focuses on the various small ligand

Table 1 NDB primary content acquired from PDB and its description

Main content of Nucleic Acids Database (NDB)	Explanation about the contents
Coordinate information	Description about the atomic coordinates for the asymmetrical and biological unit
Experimental files	The details about the <i>NMR</i> restraints and the structure factor files
Identifiers	The <i>IDs</i> for <i>NDB</i> and <i>PDB</i>
Structural description	The description about the asymmetric and biological unit, sequence, mismatches, base pairing, and modification
Citation	The details about the authors, title, journals, year, pages, volume, <i>DOI</i> , and <i>PUBMED ID</i>
Crystal data	A description about the space group information and cell parameters
Crystallization details	The conditions for temperature, <i>pH</i> , method, and crystallization
Data collection information	The information related to wavelength, temperature, radiation source, detector, resolution, <i>R</i> -merge, and number of reflections
Refinement details	Information regarding programs and method used, reflection number, resolution, <i>R</i> -factor, refinement of occupancies, and temperature factors

Table 2 Summary of the various nucleic acid databases with vivid description

Examples of Nucleic Acid Database (NDB)	Description of database
ProNIT	Provides experimentally determined thermodynamic interaction data between proteins and nucleic acids. It contains the properties of the interacting protein and nucleic acid, bibliographic information, and several thermodynamic parameters such as the binding constants, changes in free energy, enthalpy, and heat capacity
RNA FRABASE	An engine with database to search the 3D fragments within 3D RNA structures using as an input the sequences and/or secondary structures given in the dot-bracket notation
RNA Bricks	Database of RNA 3D structure motifs and their contacts, both with themselves and with proteins. The database provides structure-quality score annotations and tools for the RNA 3D structure search and comparison
RNA 3D Motif Atlas	RNA 3D motifs are recurrent structural modules that are essential for many biological functions and RNA folding. Usually drawn as unstructured hairpin and internal loops, these motifs are organized by noncanonical base pairs, supplemented by characteristic stacking and base-backbone interactions
RNAJunction	Provides a user-friendly way of searching structural elements by PDB code, structural classification, sequence, and keyword or interhelix angles. Contains structure and sequence information for RNA structural elements such as helical junctions, internal loops, bulges, and loop-loop interactions

molecules that target the RNA. At present this database contains approximately 770 unique ligands with the structural images pertaining to the RNA molecules. Also it gives information related to comprehensive resources that are required for further design, development, and refinement of small molecule modulators necessary for selective target of the RNA molecules (Mehta *et al.*, 2014).

Apart from G4LDB, there is also an important database consisting of detailed information related to the proteins' interaction with the nucleic acids forming a G-quadruplex structure, *Nucleic acid G-quadruplex structure (G4) Interacting Proteins DataBase (G4IPDB)*. This first database gives accurate knowledge related to the interaction at a single platform. It also consists of more than 200 entries with various interaction details such as interacting protein names and their synonyms, their UniProt-ID, source organism, target name and its sequences, ΔT_m , binding/dissociation constants, protein gene name, protein FASTA sequence, interacting residue in protein, related PDB entries, interaction ID, graphical view, PMID, author's name, and techniques that were used to detect their interactions. A vivid summary of the various examples of NDB with their detailed explanation is illustrated in Table 2. From the table, examples of various NDB have been described that give a clear picture about the interconnection with the nucleic acids.

Future Directions and Closing Remarks

After the redesign of NDB, new improvements can be noticed highlighting the data content that consists of derived data, annotations, and presentation. However, NDB will further continue to develop and expand its scope. The original NDB contained fewer than 100 crystal structures of nucleic acids but now has more than 700. As the technology is growing faster day by day, it will help us to observe a wide variety of structures in the NDB as it has permitted to determine number of structures. Also this database will facilitate the addition of more search options, annotations, visualizations, and various reports related to the nucleic acid-containing structures in the near future. Hence to our knowledge and information, no such database exists containing detailed experimental information related to drug-nucleic acid binding (K_d , T_m , IC_{50} , etc.,) for all the majorly available types and forms of nucleic acid. A clear view of the NDB can provide us much information related to the structure and functionality and also about the various sequences. Meanwhile the website has refurbished the information related to the query and its reporting capabilities. And this can help us to observe a wide variety of structures in the NDB as it has permitted to determine number of structures.

Biographical Sketch

Airy Sanjeev is presently working as a research scholar in the Department of Molecular Biology and Biotechnology in Tezpur University under the supervision of Dr. Venkata Satish Kumar Mattaparthi. Her research work is based on understanding the aggregation pathway of α -synuclein which is responsible for Parkinson's Disease. She has expertise in various softwares such as AutoDock, PyRex, Schrodinger, AMBER, GROMACS, and also programming languages such as Perl, Java, C, C++ . She has also skills in operating systems, protein modeling, graphing and data analysis suites, etc. She has published almost 10 papers in the peer-reviewed journals. She has completed her Masters from Pondicherry University in 2015 in Centre for Bioinformatics. She did her undergraduate work at Cotton College, Guwahati, Assam with Botany as her honors subject.

Dr. Venkata Satish Kumar Mattaparthi received his PhD in Biotechnology from Indian Institute of Technology Guwahati, Assam, India in 2010. From 2010 to 2012, he was with the Centre for Condensed Matter Theory (CCMT), Department of Physics, Indian Institute of Science Bangalore, India. He is currently working as Assistant Professor in the Department of Molecular Biology and Biotechnology, School of Sciences, Tezpur University, Assam, India. His research interests include understanding the functioning of intrinsically disordered proteins (IDPs), pathways of protein aggregation mechanism in neurodegenerative diseases like Alzheimer, Parkinson, etc., and also the features of protein–RNA interactions using computational techniques. He has published his research in reputed international journals like *Journal of Biomolecular Structure and Dynamics*, *PLoS ONE*, *Journal of Physical Chemistry B*, *Biophysical Journal*, *Journal of Bioinformatics and Computational Biology*, and others.

Dr. Sandeep Kaushik is a passionate computational biologist with a wide exposure of computational approaches. Presently, he is carrying out his research as an Assistant Researcher (equivalent to Assistant Professor) at 3B's Research Group, University of Minho, Portugal. He has a PhD in Bioinformatics from National Institute of Immunology, New Delhi, India. He has a wide exposure on analysis of scientific data ranging from transcriptomic data on mycobacterial and human samples to genomic data from wheat. His research experience and expertise entails molecular dynamics simulations, RNA-sequencing data analysis using Bioconductor (R language based package), de novo genome assembly using various software like *AbySS*, *automated protein prediction and annotation*, *database mining*, *agent-based modeling and simulations*. He has a cumulative experience of more than 10 years of programming using PERL, R language and NetLogo. He has published his research in reputed international journals like *Molecular Cell*, *Biomaterials*, *Biophysical Journal*, and others. Currently, his research interest involves in silico modeling of disease conditions like breast cancer, using agent-based modeling and simulations approach.

RNA Structure Prediction

Introduction

Three major types of RNAs, namely messenger RNA (mRNA) as coding RNA, as well as transfer RNA (tRNA) and ribosomal RNA (rRNA) as non-coding RNAs, are involved in the translation of genetic code. Among them, tRNAs fold into the common clover leaf-like secondary structure, having anti-codons that interact with the codons of the mRNAs, to perform their function as adaptors during the translation of mRNAs into proteins. Such common secondary structures are often observed in other non-coding RNAs such as snoRNAs and various snRNAs involved in splicing. It is also known that the secondary structural stability of mRNAs, especially around the start codon, affects the efficiency of translation. Micro RNAs (miRNAs) repress the translation of target mRNAs, are first transcribed as pri-miRNAs to form the stem-loop secondary structures for processing to double-stranded pre-miRNAs and then to mature miRNAs. Many non-coding RNAs other than miRNAs can be transcribed, but few of their functions have been identified. The functions of RNA molecules often depend on their high sequence specificity for interacting with other RNAs. These interactions are based on the base pairing of complementary bases, which are also observed in the secondary structures. Thus, it is important to identify the secondary structures of RNAs to elucidate and understand their functions. In this article, we introduce currently available knowledge on the structure prediction of RNAs with a particular focus on secondary structures.

A number of software tools related to RNA secondary structures are available. Researchers should select the appropriate tools for their specific purposes. It should be noted that Vienna RNA package (Lorenz *et al.*, 2011) is the most popular and convenient suite of the tools and the software libraries.

Models of RNA Secondary Structures

Secondary Structure

Single-stranded RNA molecules form hydrogen bonds between the Watson-Crick (WC) edges of the complementary pairs of bases, namely the canonical WC pairs A-U and G-C, and the wobble pair G-U. The set of base-pairs of an RNA molecule is called the secondary structure of the RNA. RNA molecules fold into tertiary structures via complicated interactions inside of the molecules, but the secondary structures are often used as abstract forms of the RNA structure. It is known that the secondary structures are often well conserved between RNAs of the same functional family.

The secondary structure of an RNA sequence $x = x_1 \dots x_L$ of the length L is represented by an upper triangle binary matrix, specifically the secondary structure matrix (2DSM), $\{\sigma_{ij}\}$ ($1 \leq i < j \leq L$) where in the secondary structure $\sigma_{ij} = 1$ shows that x_i and x_j form a base pair, $\sigma_{ij} = 0$ shows that there is no base pair between them, and σ_{ij} satisfies $\sum_i \sigma_{ij} \leq 1$ and $\sum_j \sigma_{ij} \leq 1$. The interactions of the base pairs are illustrated in Fig. 1.

Pseudoknots

Fig. 2 presents examples of non-crossing and crossing interactions in secondary structures. Secondary structures with such crossing interactions are called *pseudo-knots*. The 2DSM of a pseudoknot-free secondary structure σ_{ij} satisfies: $\sigma_{ij}\sigma_{k\ell} = 0$ if $i < k < j < \ell$. The majority of software tools for RNA secondary structure prediction only produce pseudoknot-free structures.

Fig. 1 Representations of a secondary structure (Hammerhead ribozyme). Two-dimensional (2D) representation (left), linear representation (right top) and sequence representation using parentheses (right bottom).

Fig. 2 Interactions in RNA secondary structures. The interactions of base pairs without pseudoknots (left) and with pseudoknots (right) are shown.

Fig. 3 Loops in secondary structures.

Extended secondary structures

Three-dimensional (3D) RNA structures consist of WC base pairs and non-WC base pairs and various hydrogen bonds. Such base-pairing interactions are categorized into 12 groups based on the combination of interacting edges (WC, Hoogsteen and sugar) in nucleotide bases and the relative orientations of glycosidic bonds (cis or trans) (Leontis *et al.*, 2002), which totally form the *extended secondary structures*. Among these groups, cis WC-WC base pairs are the standard WC base pairs, and the remaining 11 groups are non-WC base pairs.

Energy Models

An energy model of RNA secondary structures and their parameters define the free energy of a given RNA sequence. The most widely used energy model for pseudoknot-free 2D structures is Turner nearest neighbor model (Mathews *et al.*, 1999; Mathews, 2004). The Turner model assumes that the free energy of a secondary structure is the sum of all the *loops* surrounded by the backbone and the base-pairing hydrogen bonds, such as stacks, internal loops, bulge loops, hairpin loops, and multi-loops (Fig. 3). The free energy of the whole RNA structure is given by

$$E(x, \sigma) = \sum_{\sigma_i \in \sigma} E(\sigma_i) \quad (1)$$

The parameters of the Turner model represent the *nearest neighbors* of those loops and the length of the included nucleotides, as determined experimentally (Mathews *et al.*, 1999; Mathews, 2004).

The constraint generation (CG) method (Andronescu *et al.*, 2007) estimates Turner parameters from structural and experimental data. It applies the constraint that the reference structure has lower energy than that of alternative structures and achieved better accuracy in secondary structure prediction. Boltzmann Likelihood (BL) method for the Turner model further improved the predictive accuracy of secondary structures. The energy parameters have also been calculated by combination of experiments and molecular dynamics calculations (Sakuraba *et al.*, 2015).

The number of model parameters is the key issue in secondary structure prediction. Approximately 70,000 free parameters were used in ContextFold (Zakov *et al.*, 2011), and 50% reduction in error rate was reported, but there is serious danger for overfitting.

Boltzmann distribution

Given an RNA sequence x , the probability distribution of the secondary structure σ with free energy $E(x, \sigma)$ is written by the Boltzmann distribution,

$$P(\sigma|x) = \frac{1}{Z(x)} e^{-\frac{E(x,\sigma)}{RT}} \quad (2)$$

where $Z(x)$, the partition function of this distribution, is the sum of the Boltzmann factors for the set of all possible secondary structures S , as follows:

$$Z(x) = \sum_{\sigma \in S} e^{-\frac{E(\sigma,x)}{RT}} \quad (3)$$

This partition function $Z(x)$ can be calculated efficiently, costing $O(L^3)$ in time and $O(L^2)$ in memory for an RNA sequence of the length L , via the McCaskill algorithm (McCaskill, 1990), which is a dynamic programming (DP) method that will be explained in a subsequent section.

Stochastic Models

The Turner energy model and its parameters represent the thermodynamic character of the secondary structure and consequently define the probability via the Boltzmann distribution. Meanwhile, stochastic models can directly define the probabilities of the secondary structures. Stochastic context free grammar (SCFG) was first used to model the secondary structure of tRNA (Sakakibara *et al.*, 1994), and it has been widely used for pseudoknot-free secondary structure prediction.

For example, the following set of stochastic production rules gives a type of stochastic model of RNA secondary structure:

$$S \rightarrow xS\bar{x} \text{ with probability } P(S \rightarrow xS\bar{x}) \quad (4)$$

$$S \rightarrow x \text{ with probability } P(S \rightarrow x) \quad (5)$$

where $\bar{x}$ represents the complementary base of x . Using more complicated production rules, SCFG can represent the nearest neighbor parameters (Knudsen and Hein, 2003; Rivas *et al.*, 2012). In the stochastic models of RNA secondary structures, the set of parameters are learned from the set of RNA sequences for which the secondary structures are determined.

Do *et al.* maximized the conditional likelihood of the stochastic log-linear model for a structural dataset by using a gradient descent for optimization in their secondary structure prediction software CONTRAfold (Do *et al.*, 2006). The CONTRAfold model does not reliably determine free-energy changes, but it is important for estimating bindings.

To treat pseudoknotted secondary structures using stochastic models, formal grammars beyond context-free grammar are necessary (Rivas and Eddy, 2000). The complexity of the formal grammar depends on the complexity of pseudoknots.

Secondary Structure Prediction

We mainly treat the simplest problem in RNA secondary structure prediction to predict the secondary structure of a single RNA sequence for pseudoknot-free structures without any additional information. To solve this problems, several software tools are available, including Mfold (Zuker, 2003), RNAfold (Lorenz *et al.*, 2011), Pfold (Knudsen and Hein, 2003), RNAstructure (Mathews, 2014), CONTRAfold (Do *et al.*, 2006), CentroidFold (Sato *et al.*, 2009; Hamada *et al.*, 2009a), TurboFold (Harmanci *et al.*, 2011), and ContextFold (Zakov *et al.*, 2011).

Meanwhile, tools for pseudoknotted secondary structures including Pknots (Rivas and Eddy, 1999), IPknot (Sato *et al.*, 2011), tend to incorrectly predict pseudoknot-free structures. They are useful for finding pseudoknotted local structures, but often show lower total accuracy even for RNAs including pseudoknotted structures.

RNA secondary structure prediction is reasonably accurate for RNAs shorter than 1000, but the accuracy is often unsatisfactory for longer RNAs. The accuracy is improved using homologous sequences (Hamada *et al.*, 2009b) because the local secondary structures are often evolutionarily conserved.

There are several variations of secondary structure prediction problems, such as the prediction of suboptimal structures, the common secondary structure and alignment of a group of sequences, the common secondary structure from aligned sequences, the secondary structure of an interacting pair of sequences, and the secondary structure combining experimental data.

Criteria of Secondary Structure Prediction

Prediction of minimum free energy structures

The Boltzmann distribution Eq. (2) of the secondary structure indicates that the maximum likelihood estimator (MLE) $\hat{\sigma}^{MLE}$ of the secondary structure is the MFE structure $\hat{\sigma}^{MFE}$ as follows.

$$\hat{\sigma}^{MLE} = \operatorname{argmax}_{\sigma} P(\sigma|x) = \operatorname{argmin}_{\sigma} E(x, \sigma) = \hat{\sigma}^{MFE} \quad (6)$$

The dynamic programming algorithm proposed by Zuker and Stiegler (1981) computes the MFE/MLE structure efficiently costing $O(L^3)$ in time and (L^2) in memory. Mfold and RNAfold of the Vienna RNA package are popular tools for finding MFE structures via dynamic programming.

It is natural to believe that the MFE/MLE structures are the *best* structures we can predict, but the probability of a specific secondary structure is extremely small. For example, the probability of MFE structure of a tRNA is often less than 1%, and for

longer RNAs it is easily less than 10^{-8} . Whereas the MFE/MLE is an extremely important criterion, the MFE/MLE structures are not as reliable as they appear considering their thermodynamic probability.

Predictions Based on the Maximum Expected Accuracy

The MLE structure $\hat{\sigma}^{MLE}$ in Eq. (6) can be re-written as follows:

$$\hat{\sigma}^{MLE} = \operatorname{argmax}_{\sigma} P(\sigma|x) = \operatorname{argmax}_{\sigma} \sum_{\hat{\sigma}} \delta(\sigma, \hat{\sigma}) P(\sigma|x) \quad (7)$$

where $\delta(a,b)$ is the δ function, which is 1 only if the two parameters are equal and 0 otherwise. According to the aforementioned equation, the MLE structure, or equivalently the MFE structure, maximizes the probability that the predicted structure is exactly the same as the *true* structure. This means that no neighboring structure different from the *true* structure, is considered in the evaluation.

In CONTRAfold, which applies the criterion of MEA, the gain function, which reflects an accuracy measure of the secondary structure prediction, was used instead of using the δ function in Eq. (7) as follows:

$$G^{MEA} = TN_{\text{position}} + \gamma \times TP_{\text{position}} \quad (8)$$

where TN_{position} and TP_{position} are, the numbers of positions correctly predicted as unpaired (*true negative*), and paired (*true positive*), respectively. The γ is the sensitivity/specificity tradeoff parameter. Whereas this gain function uses the true negatives and positives with respect to the positions, the accuracy of secondary structure prediction has been usually measured using the number of correctly paired/unpaired *base pairs* which CentroidFold adopted in its gain function

$$G^{\gamma} = TN_{\text{base-pair}} + \gamma \times TP_{\text{base-pair}} \quad (9)$$

Marginal Probabilities and Reliability of Predictions

Marginal Probabilities of Secondary Structures

Although the probability that an RNA sequence will form a specific secondary structure is extremely small, the marginal probabilities of the structure are often reasonably large. The most popular marginal probability is the base-pairing probability (BPP), or the probability that the specific pair of bases form a base pair in the secondary structure. BPPs include rich information regarding the probability distribution of the RNA secondary structure. They are often illustrated in an upper triangular matrix (Lorenz *et al.*, 2011) suggesting the existence of hidden alternative structures, or presented on the predicted secondary structure with colors that illustrate the reliability of the stem structures.

The marginal probabilities of various structural contexts, such as stems, loops, and bulges, also carry rich information about the secondary structure. Although it is difficult to detect distinct structural motifs from a set of functional RNAs, local pattern of marginal probabilities has been observed (Fukunaga *et al.*, 2014).

Reliability of Predicted Structures

The accuracies of predictions for secondary structures are often evaluated regarding the accuracy of base pair prediction using sensitivity (SEN, or recall), the positive predicted value (PPV, or precision) and balanced measures such as Matthew's correlation coefficient (MCC) and F-measures, defined as follows.

$$\text{SEN} = \frac{TP}{TP + FN} = \frac{\# \text{ of correctly predicted base - pairs}}{\# \text{ of true base - pairs}} \quad (10)$$

$$\text{PPV} = \frac{TP}{TP + FP} = \frac{\# \text{ of correctly predicted base - pairs}}{\# \text{ of predicted base - pairs}} \quad (11)$$

$$\text{MCC} = \frac{TP \cdot TN + FT \cdot FN}{\sqrt{(TP + FP)(TP + FN)(TN + FP)(TN + FN)}} \quad (12)$$

$$\text{F-measure} = 2 \frac{\text{PPV} \cdot \text{SEN}}{\text{PPV} + \text{SEN}} \quad (13)$$

Whereas base-pairing probabilities are convenient for partially representing the probability distribution, they do not clearly reveal the entire picture of the distribution. RNAbor (Freyhult *et al.*, 2007) computes the marginal probability of secondary structures on the Hamming distance from the reference structure. Mori *et al.* (2014) has formalized the calculation of Distribution of the Hamming distance based on the general scheme proposed by Newberg and Lawrence (2009). When the sum of the probabilities within a range of Hamming distance exceeds $c\%$, the smallest such Hamming distance is called the $c\%$ *credibility limit*. A lower credibility limit with a higher percent indicates that the distribution is more concentrated, and that the prediction is more reliable.

Algorithms on RNA Secondary Structures

Dynamic Programming Algorithms

As described previously, pseudoknot-free RNA secondary structure can be modeled using SCFGs corresponding to pseudoknot-free energy models. The DP algorithms for pseudoknot-free RNA secondary structures therefore corresponds to the standard SCFG algorithms.

Dynamic programming for partition function

The partition function Eq. (3) of the Boltzmann distribution Eq. (2) can be calculated by the McCaskill algorithm (McCaskill, 1990), a DP algorithm corresponding to the inside algorithm of SCFG.

The McCaskill algorithm

Initialization: for $1 \leq i \leq N$

$$Z_{i,i} = 1.0, \quad Z_{i,i}^1 = Z_{i,i}^b = Z_{i,i}^m = Z_{i,i-1}^m = Z_{i,i}^{m1} = 0.0$$

Recursion: for $1 \leq i < j \leq N$ (from short intervals to long intervals)

$$Z_{i,j} = 1.0 + \sum_{h=i-1}^{j-1} Z_{i,h} Z_{h+1,j}^1 \quad (14)$$

$$Z_{i,j}^1 = \sum_{h=i+1}^j Z_{i,h}^b$$

$$\begin{aligned} Z_{i,j}^b = & e^{-f_1(i,j)/kT} + \sum_{h=i+1}^{j-2} \sum_{\ell=h+1}^{j-1} Z_{h,\ell}^b e^{-f_2(i,j,h,\ell)/kT} \\ & + \sum_{h=i+2}^{j-1} Z_{i+1,h-1}^m Z_{h,j-1}^{m1} e^{-f_3(i,j)/kT} \end{aligned} \quad (15)$$

$$Z_{i,j}^m = \sum_{h=i+1}^{j-1} (e^{-f_4(i,h-1)/kT} + Z_{i,h-1}^m) Z_{h,j}^{m1} e^{-f_5/hT} \quad (16)$$

$$Z_{i,j}^{m1} = \sum_{h=i+1}^j Z_{i,h}^b e^{-f_4(h+1,j)/kT}$$

$Z_{i,j}$ is the partition function of subsequence $[i, j]$, $Z_{i,j}^b$ is that of i - j base pairing, and $Z_{i,j}^m$ is that of multi-loop. $Z_{i,j}^1$ and $Z_{i,j}^{m1}$ are the partitions functions that include exactly one outmost base pair. The functions f_1 to f_5 reflect the free energy of unpaired bases, depending on the structural contexts.

Dynamic programming for MFE

The first reported DP algorithm for secondary structure prediction was the Nussinov algorithm (Nussinov *et al.*, 1978). It maximizes the number of base pairs in the secondary structure, which we can regard as a rough approximation of MFE, by iterating the following equations from short intervals to long intervals:

$$M(i,j) = \max \begin{cases} M(i+1, j) \\ M(i, j-1) \\ M(i+1, j-1) + 1 \text{ if } (i,j) \text{ can form a base pair} \\ \max_h M(i, h) M(h+1, j) \end{cases}$$

The Nussinov algorithm correspond to the CYK algorithm (Kasami *et al.*, 1965; Younger, 1967) for the parsing of SCFGs. with complexities $O(L^3)$ in time and $O(L^2)$ in memory for the length L of the sequence. Assuming a Turner type energy model for pseudoknot-free structures, MFE structures can be calculated via Zuker algorithm (Zuker and Stiegler, 1981), a CYK-like DP algorithm, using more complicated iterations, but with complexities $O(L^3)$ in time and $O(L^2)$ in memory.

DP for Base-Pairing Probability

The BPP of RNA is the marginal probability that a specific pair of bases will form a base pair in the secondary structure. BPPs are calculated using inside/outside partition functions as follows:

$$P_{i,j}^b = \frac{Z_{ij}^b W_{ij}^b}{Z_{1L}}$$

where Z_{ij}^b is the *inside* partition function of subsequence $[i, j]$ when the i -th and j -th bases form a base pair, which appeared in Eq. (15) of the McCaskill algorithm, and W_{ij}^b is the corresponding *outside* partition function, which is the sum of all the Boltzmann factors outside of $[i, j]$ when the i -th and j -th bases form a base pair. The $W^b(i, j)$ is calculated by a DP algorithm, which is the outside algorithm of the McCaskill (inside) algorithm for partition function. A DP algorithm that directly calculate BPPs similar to outside algorithm for $W^b(i, j)$ was reported in the same study reporting the McCaskill algorithm (McCaskill, 1990).

The computational complexity of those DP algorithms is also $O(L^3)$ in time and $O(L^2)$ in memory. For long RNA sequences, $O(L^3)$ in time and $O(L^2)$ are too expensive for practical analysis. By limiting the maximal span of base pairs to W , Rfold (Kiryu *et al.*, 2008) reduces them to $O(W^2L)$ in time and $O(L + W^2)$ in memory. The Rfold algorithm has been extended to parallel computations in ParasoR (Kawaguchi and Kiryu, 2016), including calculations of marginal probabilities implemented in CapR (Fukunaga *et al.*, 2014). Because $O(W^2L)$ is linear with respect to sequence length L , these tools are applicable for analyzing long non-coding RNAs.

Posterior Decoding for Maximum Expected Gain Prediction

As described in Predictions Based on the Maximum Expected Accuracy (MEA), predictions based on MEA are maximum expected gain estimators with the associated gain functions. The MEA estimator of CONTRAfold and the γ -centroid estimator of CentroidFold are calculated by the using dynamic programming as follows (Do *et al.*, 2006):

$$M(i, j) = \max \begin{cases} M(i+1, j) \\ M(i, j-1) \\ M(i+1, j-1) + g(\gamma, P_{ij}^b) \\ \max_h M(i, h)M(h+1, j) \end{cases}$$

where $g(\gamma, P_{ij}^b) = 2\gamma P_{ij}^b - (1 - \sum_i P_{ij}^b) - (1 - \sum_j P_{ij}^b)$ for the MEA estimator, and $g(\gamma, P_{ij}^b) = (\gamma + 1)P_{ij}^b - 1$ for the γ -centroid estimator. P_{ij}^b is the BPP.

Such DP is called *posterior decoding* of the marginal probability. Note that the DP in this case is extremely simple and similar to the Nussinov algorithm.

Additional Information on Secondary Structure Prediction

RNA Secondary Structure Prediction Incorporating Experimental Data

In recent decades, experimental investigations have been common approaches for understanding RNA structures. In the experimental approaches, recently emerging high-throughput sequencing technology changed the scale of target RNAs from a single transcript to the whole transcriptome. Currently, experimental investigations of RNA structures are categorized into the following two approaches: (1) *in vitro/in vivo* probing of RNA base pairs, (2) *in vivo* probing of RNA duplexes.

In the first approach, the pairing state (paired or unpaired) of individual bases in RNA molecules is analyzed using chemical and enzymatic probing. Selective 2'-hydroxyl acylation analyzed via primer extension and sequencing (SHAPE-seq) (Loughrey *et al.*, SHAPE; Lucks *et al.*, 2011), SHAPE and mutational profiling (SHAPE-MaP) (Siegfried *et al.*, 2014; Smola *et al.*, 2015), *in vivo* click selective 2'-hydroxyl acylation and profiling experiment (icSHAPE) (Flynn *et al.*, 2016; Spitale *et al.*, 2015), Structure-seq (Ding *et al.*, 2015), dimethyl sulfate (DMS) treatment and sequencing (DMS-seq) (Rouskin *et al.*, 2014), DMS mutational profiling with sequencing (DMS-MaPseq) (Zubradt *et al.*, 2017), Mod-seq (Talkish *et al.*, 2014), and chemical inference of RNA structures followed by massive parallel sequencing (CIRS-seq) (Incarnato *et al.*, 2014) are categorized as chemical probing methods employing various chemical compounds reacting with unpaired nucleotides (single-stranded regions) in RNA molecules. Fragmentation sequencing (Fragseq) (Underwood *et al.*, 2010), parallel analysis of RNA structure (PARS) (Kertesz *et al.*, 2010; Wan *et al.*, 2014) and parallel analysis of RNA structures with temperature elevation (PARTE) (Wan *et al.*, 2012) are enzymatic probing methods using structure-specific RNase, including RNase V1 and S1, for identifying both paired and unpaired nucleotides. For all of the aforementioned methods, raw sequencing reads must be processed to obtain the base-pairing or single-stranded signals of RNA bases at single-nucleotide resolution. The signal data derived from the limited number of structure probing experiments, such as icSHAPE and DMS-seq, is pre-computed and provided by Structure Surfer database (Berkowitz *et al.*, 2016) and FoldAtlas (Norris *et al.*, 2017).

As the second approach, RNA proximity ligation (RPL) (Ramani *et al.*, 2015), psoralen analysis of RNA interactions and structures (PARIS) (Lu *et al.*, 2016), ligation of interacting RNA and high-throughput sequencing (LIGR-seq) (Sharma *et al.*, 2016), sequencing of psoralen crosslinked, ligated and selected hybrids (SPLASH) (Aw *et al.*, 2016), and mapping RNA interactome *in vivo* (MARIO) (Nguyen *et al.*, 2016) employ proximity ligation of RNA duplexes to directly identify two RNA regions involved in base-pairing interactions.

The base-pairing or single-stranded signals derived from the probing experiments can be combined with computational prediction of RNA secondary structures to improve their prediction accuracy. In MC-fold prediction (Parisien and Major, 2008), three grades of energetic penalties are applied according to the SHAPE signal of each nucleotide. RNAstructure (Deigan *et al.*, 2009), RNAsc (Zarringhalam *et al.*, 2012), and RNAbifold (Washietl *et al.*, 2012) incorporate the signal data into their energy calculation as pseudo-energy contribution. Currently, these three approaches are also implemented in the RNAfold Vienna RNA package (Lorenz *et al.*, 2016). As a sampling-based approach, Seqfold (Ouyang *et al.*, 2013) was developed for incorporating various type of probing data, such SHAPE-seq, PARS, and FragSeq data.

Non-DP Algorithms

Stochastic sampling

In order to estimate marginal probabilities of the secondary structures of RNA, stochastic sampling can be used (Ding and Lawrence, 2003). In stochastic sampling, the structures are sampled from Boltzmann distribution of the secondary structures.

Integer programming

It is computationally expensive to predict pseudoknotted secondary structures using DP algorithms. Integer programming has been used to predict pseudoknotted secondary structures in IPknot (Sato *et al.*, 2011). Predicting the joint secondary structure of two interacting RNA sequences has the same computational complexity as pseudoknotted secondary structure prediction, and integer programming has been applied in RactIP (Kato *et al.*, 2010).

Common Secondary Structure Prediction

RNA secondary structures often conserved during evolution. Therefore, it is important to detect the common secondary structure of the related sequences and find the functions correlated to the secondary structures. Several tools exist for locating the consensus secondary structures from multiple alignments of RNA sequences, such as CentroidAlifold (Hamada *et al.*, 2011) and RNAalifold (Bernhart *et al.*, 2008). PPFold (Sukosd *et al.*, 2012) incorporates SHAPE data in predicting the consensus secondary structures. The aforementioned tools require multiple alignments of RNA sequences to detect common secondary structures. As inputs of those tools, we can use RNA structural multiple alignment tools, which find the multiple alignments considering secondary structures, such as MAFFT (Kato and Toh, 2008), LocARNA (Will *et al.*, 2012), LARA (Bauer *et al.*, 2007), MXSCARNA (Tabei *et al.*, 2008), and CentroidAlign (Hamada *et al.*, 2009c).

Joint Secondary Structures Prediction

Functional RNAs interact with other molecules to perform their functions. Predictions of the joint secondary structures of two RNA molecules require predictions of inter-molecular and intra-molecular base pairs. RactIP (Kato *et al.*, 2010) and IntaRNA (Busch *et al.*, 2008) efficiently predicts joint secondary structures. PETcofold (Seemann *et al.*, 2011) predicts the conserved joint secondary structures.

Prediction of RNA Three Dimensional Structure

Accurate prediction of the 3D structures of RNA molecules is one of the most challenging problems in the RNA bioinformatics field. In the RNA-Puzzles (Cruz *et al.*, 2012; Miao *et al.*, 2015, 2017), a community-wide blind test for RNA 3D structure prediction, most participant groups could not predict near-native structures for several problems (target RNA molecules). RNA 3D structures consist of not only WC base-pairs but also non-WC base-pairs and various hydrogen bonds, in contrast to RNA 2D structures, which are simply constructed from WC base-pairs. Currently, base-pairing interactions are categorized into 12 groups based on the combination of interacting edges (Watson-Crick, Hoogsteen and sugar) in nucleotide bases and the relative orientations of glycosidic bonds (cis or trans) (Leontis *et al.*, 2002). Among these groups, cis WC-WC base-pair are known as standard WC base pairs, and the remaining 11 groups are non-WC base-pairs. Currently, there are two types of 3D structure prediction methods: template-based and physical chemistry-based methods.

In template-based methods, small structural elements derived from several known structures, referred to modules/motifs or templates, are assembled to construct a predicted structure as building blocks. These structural modules or motifs contain many non-WC base pairs. An appropriate selection of these structural modules leads to accurate prediction of the RNA 3D structures. Template sizes and template selection methods depend on the prediction software. As the largest template-based methods, ModeRNA (Rother *et al.*, 2011) and RNABuilder (Flores *et al.*, 2010) use the whole structures as the templates for their predictions. MC-fold/MC-sym (Parisien and Major, 2008), RNAComposer (Popenda *et al.*, 2012) and 3dRNA (Zhao *et al.*, 2012) employ medium-sized templates derived from small elements in RNA secondary structures that are computationally predicted or provided by users. FARNA (Das and Baker, 2007) is a fragment assembly method, which is also known as ROSETTA framework in protein

structure prediction fields, which uses a few nucleotides as fragments. The FARNAs-predicted structures could be refined at atomic resolution using FARFAR (Das *et al.*, 2010).

In physical chemistry-based methods, each nucleotide of an input RNA sequence is represented with coarse-grained beads instead of the full atoms in 3D space. Monte Carlo simulation or molecular dynamics simulation is used for conformational sampling of the coarse-grained RNA structure. There are two types of energy function for scoring the simulated (predicted) structures. The first type is knowledge-based statistical potential derived from known 3D structures as employed in SimRNA (Boniecki *et al.*, 2016). The second type of energy function is based on physicochemical interactions, such as hydrogen bonds of base pairing and electrostatic repulsion of the phosphates, implemented in HiRE-RNA (Cragnolini *et al.*, 2015). These methods could provide accurate predictions for small (10–20 nucleotides) to medium (50–80 nucleotides) of RNA molecules, whereas an application of these methods to moderately large (> 100 nucleotides) RNA molecules remains challenging. The physical chemistry-based methods require high computational cost for efficient conformational sampling of RNA structures.

Conclusion

The structures of RNAs are important for understanding their functions. Among them, RNA secondary structures are important and well studied. Most functional RNAs interact with other RNAs via complementary base pairing, which complete the intra-molecule interactions that form the secondary structures. The minimum free energy secondary structures are usually selected as the predicted structures, but the MEA estimator or gamma-centroid estimator have higher expected accuracy with respect to the number of correctly predicted base-pairs. Recent progress in experiments has allowed us to incorporate the experimentally predicted base pairs into computational predictions of the secondary structures. Even if using experimental data, the probabilities of the predicted secondary structures remain low because the number of possible secondary structures are large. The marginal probabilities, such as base-pairing probabilities, represent structurally important information, and they are not necessarily low. Predicting pseudoknotted structures, the interactions of two RNA molecules, the common secondary structures of two RNA sequences, are all computationally expensive if the strict DP algorithms are applied, but stochastic sampling or integer programming is often useful.

Computational methods have been developed for RNA secondary structures, and they are becoming useful for the structural analysis of RNA. Although the point estimations of RNA secondary structures have limited reliability, we can understand the total picture of the secondary structures via combinations of bioinformatics tools. The probability distribution of Hamming distance and the credibility limits are relevant examples. The prediction of the 3D structures remains challenging, but its accuracy is expected to improve due to the increased availability of experimentally validated 3D structures.

Introduction

The discovery, optimization and evaluation of small molecules which interact with a biological target of pharmaceutical relevance is the core of the drug discovery process. So far, this has been mostly dominated by the conventional brute-force approach of lead discovery via high throughput screening (HTS) of the natural product, synthetic or combinatorial compound libraries to identify potential leads (Macarron *et al.*, 2011). While effective in many cases, HTS is expensive, requires a readily available diverse set of compounds to screen, often yields hits with poor efficacy and provides little information to guide further optimization. This has driven the development of more rational and cost-efficient screening methods. The advancement in molecular biology, crystallographic techniques and computational power over the last 30 years have provided researchers access to high-quality structural information on a wide variety of biological targets. Structural information is the ultimate rational drug design tool which can streamline all aspects of drug discovery from target selection to lead optimization and can significantly reduce the development cost. Indeed, structure-guided drug design efforts have led to the discovery of many high profile drugs including amprenavir (Agenerase) and nelfinavir (Viracept) developed against the HIV protease (Kaldor *et al.*, 1997), zanamivir (Relenza) against neuraminidase (Varghese, 1999), imatinib mesylate (Gleevec) which inhibits Abl tyrosine kinase (Schindler *et al.*, 2000), erlotinib (Tarceva) for the treatment of metastatic lung cancer (Pollack *et al.*, 1999) and the thrombin inhibitor ximelagatran (Exanta) as an oral anticoagulant (Gustafsson *et al.*, 2001). More recently, lapatinib, an ErbB2 inhibitor for cancer, sitagliptin (Januvia) for type-2 diabetes, vorinostat (Zolinza) to inhibit histone deacetylase, and rivaroxaban, as an oral Factor Xa inhibitor are examples of successful application of rational structure-based methods in drug development.

Structure-based drug design (SBDD) is the process in which novel drug-like molecules are designed based on structural knowledge of the relevant macromolecular target (Wang *et al.*, 2016). In SBDD, virtual chemical libraries containing millions of compounds and structural data of macromolecules are used in tandem to assess the ability of compounds to interact with the target of interest. Many virtual libraries are publicly available, a few notable examples being PubChem (Kim *et al.*, 2016), ChEMBL (Bento *et al.*, 2014), BindingDB (Gilson *et al.*, 2016), DrugBank (Law *et al.*, 2014) and ZINC (Irwin *et al.*, 2012). In addition to public sources, commercial vendors (Maybridge, Enamine) maintain virtual libraries. Structural information on biological targets can be obtained from Protein Data Bank (PDB) (Parasuraman, 2012). If the structure of the desired target is not available, it may be possible to create a homology model using related structures available in PDB. In either case, the compounds in the virtual library are subsequently docked into the binding cavity of the target to determine the relative rank for the entire dataset. Automatic and manual data analysis of the docking result is then carried out to predict the compounds with highest binding affinity to the target. This results in a smaller subset of compounds as a starting point for downstream analysis.

This article summarizes the process of structure-based drug design and discusses the choice of target, lead identification and the various docking-based methods. Key concepts in SBDD will be illustrated through a case study that explores the identification of potential novel anti-malarial agents targeting the hemoglobin degrading enzyme, Plasmeprin II, of *Plasmodium falciparum*. The aim of this article is to guide novice computational users by elucidating the general steps involved in such a drug discovery exercise.

Background and Overview of the Process

The process of drug discovery and development generally requires extensive examination of target proteins and potential drug-like compounds before a lead is ready for phase 1 clinical trials. The first stage is identification, purification and structure determination of the target (usually a protein). The selection of the target is the most crucial step as it sets the course for all future aspects of research in the drug discovery pipeline. Once the biological target has been selected, its structure is determined by one of three methods: *X-ray diffraction* generally known as *X-ray crystallography*, *nuclear magnetic resonance spectroscopy* generally known as *NMR* and *comparative modeling* generally known as *in silico homology modeling*. In the second stage, computational techniques are used to screen and rank compound or fragment libraries based on their electrostatic and steric interaction with the target. Promising hits are then tested in biological assays to identify the compounds with desired activity (lead discovery). Once a candidate series has been identified, the lead optimization stage begins. In this stage, key lead compound properties like adsorption, metabolism, distribution and excretion are optimized while avoiding risk of toxicity. Further steps include synthesis of the optimized leads, testing, determination of the target lead complex and additional optimization. After several rounds of the process, optimized compounds usually show marked improvement in these pharmacokinetic properties and specificity for the target. The lead optimization stage usually concludes with the successful demonstration of *in vivo* efficacy of the compound in an appropriate animal model.

Rational Structure-Based Drug Design

Choice of the Drug Target and Structure Determination

The choice of the target protein is primarily made based on therapeutic and biological relevance. The 'druggable' target is a protein, peptide or nucleic acid whose activity can be modulated by a small molecule (Owens, 2007). Proteins are often used as drug targets due to their significant role in metabolic or signaling pathways specific to a disease condition and can either be activated or inhibited by small molecule drugs. Once the target has been identified it is essential to determine its three-dimensional (3D) structure ideally with a well-defined drug binding pocket to enable high throughput virtual screening in the SBDD approach. The structure of the target can be determined by one of the following methods:

X-ray crystallography and NMR

Both X-ray crystallography and NMR produce data on the relative position of atoms of a molecule. The basis of X-ray crystallography is the scattering of X-rays from electron clouds of atoms whereas NMR measures the interaction of atomic nuclei. The end-product of crystallographic structure determination is an electron density map which is essentially a contour plot indicating positions in the crystal structure where electrons are most likely to be found. This data must be interpreted in terms of a 3D model using semi-automatic computational methodologies. On the other hand, the end-product of an NMR experiment is usually a set of distances between atomic nuclei that define both bonded and non-bonded close contacts in a molecule. These must be interpreted manually to produce a 3D molecular structure using computational tools. The structure determination in each case requires assumptions and approximations, hence the resulting molecular structures obtained may have errors. The choice of technique depends on many factors including molecular weight, ease of solubility and crystallization of the macromolecule under study. X-ray crystallography remains the main workhorse of structure determination for SBDD. Currently, the RCSB Protein Data bank (Parasuraman, 2012) database contains over 130,000 structures of which 90% were solved through X-ray crystallography (Fig. 1).

Homology modeling

In the absence of an experimentally determined 3D structure of a protein, *in silico* homology modeling can provide structural models that are comparable to the best results achieved experimentally. In general, 30% target-template sequence identity is required to generate a useful structural model (Forrest *et al.*, 2006). This allows researchers to use the generated *in silico* models for

Fig. 1 Incremental increase in the structures of macromolecules in PDB database since year 2000. (Data obtained from PDB).

functional analysis and to predict interactions with other molecules. Homology modeling predicts the structure of the target protein primarily by aligning the target sequence called a query with the sequence of one or more known structures called templates and is based on two major assumptions:

1. The structure of a protein is encoded in its sequence thus knowing the sequence should at least, in theory, suffice to obtain the structure. This observation was elegantly demonstrated by Anfinsen when he showed that bovine pancreatic ribonuclease, following exposure to a denaturant, could spontaneously regain its native folded structure (Anfinsen, 1973).
2. The structure of a protein is more stable and conserved than its sequence. Therefore, closely related similar sequences will essentially adopt similar structures and more distantly related sequences will at least have similar folding, a relationship first identified by Chothia and Lesk (1986).

In practice homology modeling is a multistep process which can be summarized in the following seven steps: a). Template identification, b). Alignment correction, c). Model building d). Loop modeling, e). Side-chain modeling f). Model optimization and g). Model validation. A comprehensive review of homology modeling is beyond the scope of this article. However, interested readers are referred to a series of publications and reviews on homology modeling (Eswar *et al.*, 2006; Fiser and Sali, 2003; Martí-Renom *et al.*, 2000). A list of tools for homology modeling are given in Table 1. Repositories such as Protein model portal (Arnold *et al.*, 2009), Modbase (Pieper *et al.*, 2011) and SWISS-MODEL (Kiefer *et al.*, 2009) contain proteins models generated using various methods.

Identification of Binding Site

Once the 3D structure of the target protein is generated, its potential ligand binding sites are determined to facilitate docking computation and virtual screening (VS). Typically, the ligand binding site is a pocket with a variety of potential hydrogen bond donors, acceptors, hydrophobic characteristics and a well-defined stereochemical arrangement. The ligand binding site can be the active site where the substrate binds or can be an assembly site where another macromolecule binds or a communication site necessary to relay the information. Although empirical data suggest that actual ligand binding sites tend to coincide with the largest and deepest pockets on the target surface (Weisel *et al.*, 2007), there exist cases where ligands are known to bind exposed and shallow clefts (Nisius *et al.*, 2012). Due to the importance of binding sites in molecular recognition and interaction, a large number of computational methods for binding site recognition and analysis have been developed that scan the surface of the target for cavities or pockets which might be potential binding sites. All these methods take a target structure as input and then output an ordered list of putative binding sites. Generally, not all reported sites correspond to true binding sites, however, it is expected that entries at the top will correspond to regions with a higher probability of being true binding sites. The methods can be broadly divided into sequence-, structure- and energy-based methods.

Sequence-based methods

Sequence-based methods are based on evolutionary conservation and exploit the propensity of conserved residues in the binding site. In the LIGSITE_{Esc} algorithm (Huang and Schroeder, 2006) a sequence conservation measure of neighboring residues is used to re-rank the top three sites predicted by LIGSITE (explained under structure-based methods), which leads to an improved success rate in binding site prediction. Unlike LIGSITE_{Esc}, in ConCavity (Capra *et al.*, 2009) the conservation information is not only used to re-rank the predictions but is also incorporated into the binding site detection procedure.

Structure-based methods

In contrast to sequence-based methods, structure-based method predict ligand binding site by analyzing geometrical features like clefts or cavities. Some methods are solely based on geometrical features (LIGSITE (Hendlich *et al.*, 1997), PocketPicker (Weisel *et al.*, 2007)) while others take into account additional features like physicochemical information, polarity or charge (Fpocket (Le Guilloux *et al.*, 2009), SiteFinder by MOE (Locating Binding Sites in Protein Structures, 2017)).

Energy-based methods

Energy-based methods depend on the calculation of interaction energy between various probes placed on the grid points around the target surface and subsequent clustering of the probes with low interaction energy to identify the most energetically favorable binding pockets. Notable examples of energy-based methods are Q-SiteFinder (Laurie and Jackson, 2005) and SiteHound (Ghera and Sanchez, 2009).

Consensus method

A consensus method is essentially a meta approach that combines results from several algorithms mentioned above. For example, Metapocket 2.0 (Huang, 2009) collects results of eight different methods by taking the top three sites from each method with the authors demonstrating that Metapocket 2.0 performs better than any one individual method alone.

For a detailed review of binding site prediction methods, readers can refer to Henrich *et al.* (2010), Nisius *et al.* (2012), Xie and Hwang (2015).

Molecular Docking Based Virtual Screening

Once the structure and the target site are determined, molecular docking based virtual screening of compound and fragment libraries can be carried out to identify potential leads. VS is regarded as a computational counterpart of the experimental high-throughput screening method and is one of the most widely used strategies for SBDD (Stahura and Bajorath, 2004). The major advantage of docking approaches is their speed and the guidance they provide to follow-on wet lab experiments (López-Vallejo *et al.*, 2011). Molecular docking is also useful in the study of ligand-target interactions as the docking programs can analyze the microscopic atomic interactions between a ligand and a target.

In VS, typically a database of small molecules is docked onto the region of interest and is scored based on the predicted interactions with the site. However, in the fragment based approach, small drug-like fragments such as benzene rings, amino, hydroxy, carbonyl or other functional groups can be positioned, scored, optimized in the binding site and finally linked *in silico* to generate lead candidates. The compounds obtained *in silico* by linking fragments can then be synthesized and tested. In general, molecular docking based VS consists of several steps; (i) target preparation, (ii) compound or fragment database selection, (iii) molecular docking, (iv) post-docking evaluation analysis, and (v) molecular dynamics and binding free energy calculation. Careful and thorough literature survey regarding the target, binding site and known ligands (if available) is often necessary to select the docking algorithms best suited for the given target.

Target preparation

The preparation of the target protein requires great care because experimentally determined structures frequently have many problems like incomplete side chains, missing loops and result in inaccurate models due to incorrect interpretation of the experimental data. Structural characterization of the targeted protein includes a choice of tautomeric forms of histidine residues, correct assignment of protonation states of amino acids and conformation of residues, especially in the binding site. It is also important to add missing hydrogen atoms, build missing residues or loops, identify overlapping atoms to reduce clash and optimize hydrogen bonding network. Water molecules and cofactors (metal) in the protein active site may need to be removed or retained (if they are known to be critical for ligand binding). Metals and cofactors which form an integral part of the binding interaction with the ligand are considered part of the docking site and hence are retained. If the software allows for flexible docking in order to account for conformational changes during ligand binding, the number, the identity of flexible residues and degrees of flexibility needs to be defined.

Compound library preparation

Prior to generating the 3D structure of the library of ligands, it is important to clean up the 2D structures by removing the ions, salts, incomplete structures, inorganic molecules, duplicates and water molecules. All reactive, promiscuous and otherwise undesirable compounds should also be removed. Additionally, compounds may be filtered based on several physicochemical

Table 2 List of publically available databases of chemical compounds

parameters such as molecular weight, number of hydrogen bond acceptors, number of hydrogen bond donors, number of rotatable bonds and log P to increase the bioavailability of the remaining compounds (Doak *et al.*, 2014; Lipinski, 2000). Ligands should also be checked for proper valence states and geometry, including reasonable bond distances and angles. Energy minimization and protonation of ligands should also be performed to achieve correct ligand-protein binding (ten Brink and Exner, 2009). Table 2 list the major organizations which maintain the public repositories of chemical compounds from where 2D and 3D structures can be obtained for molecular docking.

Molecular docking

Molecular docking is a method which predicts the preferred relative orientation of one molecule (key) when bound in an active site of another molecule (lock) to form a stable complex such that free energy of the overall system is minimized. It exploits the concept of molecular shape and physicochemical complementarity. The structures interact like a hand in a glove, where both shape and physicochemical properties contribute to the fit. Molecular docking process can be separated into two major steps i) searching and ii) scoring.

Search algorithm

The search algorithm implemented in any docking tool should enumerate an optimum number of ways two molecules can be put together. The size of the search space grows exponentially with the increase in the size of the molecules. For example, the number of possible conformations for a small molecule with 10 rotatable bonds with 30 degrees of increments are 10^{12} . If the target protein is also allowed to be flexible, this quickly becomes an intractable problem. Docking applications frequently employ one or more of the following search algorithms; Simulated Annealing, Fast shape matching, Incremental construction, Particle Swarm optimization and Evolutionary algorithms (Heberlé and de Azevedo, 2011).

Scoring functions

The scoring function measures and ranks the binding of a ligand-receptor complex. It is therefore not only important to have an efficient, accurate scoring function that gives the best rank to true bound structures, but it must give the correct relative rank of each ligand in the database. Ideally, the score should directly correspond to the binding affinity of the ligand for the protein so that the top scoring compounds are also the best binders. There are three main types of scoring functions that are used by various docking programs; 1) Force field based – GLODscore, DOCK, AutoDOCK derived from AMBER and CHARMM; 2) Empirical scoring – PLP, CHemscore, Glide SP/XP and PLANTSchemplp and PLANTSplp and 3) Knowledge-based – PMF, DrugScore and its derivatives DrugScoreCSD, Astex statistical potential.

For a detailed review of molecular docking, the reader can refer to the following publications (Halperin *et al.*, 2002; Meng *et al.*, 2011; Yuriev and Ramsland, 2013). A substantial number of docking tools are now available which have been applied for discovery of novel bioactive molecules. Table 3 summarizes basic features, license terms, algorithms and scoring functions of currently available docking software. The list is not exhaustive as many docking tools have become available in recent years. Selecting a particular docking tool is always a challenge. In one study it was reported that AutoDock offered a combination of accuracy and speed as opposed to other methods for prediction of protein kinase inhibitors (Buzko *et al.*, 2002). Kellenberger *et al.* (2004) when compared the performance of eight docking programs to recover the X-ray poses of 100 ligands, they reported that GLIDE, GOLD and SURFLEX had the best docking accuracy. Therefore, choosing a docking program largely depend upon the protein family under consideration.

FlexX	Commercial	Incremental construction algorithm for protein ligand docking	https://www.biosolveit.de/FlexX/	Kramer <i>et al.</i> (1999)

The individual docking procedure associated with different docking tools may differ, for example, formats of the ligands and target files, scoring functions and algorithms for ligand placement or the ligand may be docked in entirety or in fragments. However, the general principles of docking remain similar; compounds are first placed inside the binding pocket using the algorithm implemented by the docking software and then evaluated for non-covalent interactions using a scoring algorithm available in the same package. If the position of the ligand is known *a priori*, this information can be exploited during and after the docking process. Some programs such as DOCK allow an anchor fragment, ligand placement can thus be guided during the docking process.

Post-docking evaluation and analysis

The output of docking and scoring is a ranked list of predicted bound ligands. Using computer graphics software, these can be visually evaluated for goodness of fit, the formation of key hydrogen bonds, electrostatic interactions, surface complementarities and stability of the bound conformation compared to free conformation. Compounds that get selected in the initial run are then subjected to further *in silico* optimization using focused libraries of potential ligands. Furthermore, the 3D structure of the complex comprising the target protein and the compound is often determined experimentally in order to validate the binding mode predicted by the docking software. Eventually, several high scoring ligands are purchased or synthesized and evaluated for binding and biological activity in the wet lab.

Molecular dynamics and binding free energy calculation

Molecular dynamics (MD) is a technique where the time evolution of a set of interacting atoms is followed by numerical integration of Newton's equation of motion (Adcock and McCammon, 2006). The field of MD simulations is rapidly progressing with improvement in simulation methodology and increasing accuracy of bio-molecular force fields (Hansson *et al.*, 2002). Experiments that are difficult or even impossible to perform in the wet lab can be simulated using MD. From a drug discovery perspective, MD simulation can be used to study the stability of docked complexes and to ensure that molecular docking has

yielded accurate results. The stability of the docked complex is often estimated using the root mean square deviation (RMSD) and root mean square fluctuation (RMSF) during the period of the simulations (Kuzmanic and Zagrovic, 2010). RMSF values are calculated to study the thermal stability and structural flexibility (Kuzmanic and Zagrovic, 2010) while the RMSD value measures the changes in the structure during simulation. Changes in the order of 1–3 Å are considered acceptable.

Limitations of molecular docking

Docking protocols are the combination of search algorithms and scoring functions. The scoring function is a mathematical construct that is used to calculate the strength of non-covalent interactions or binding affinity (Halperin *et al.*, 2002). Some docking experiments fail due to the inability of docking methods to account for conformational changes that occur during the binding process of protein and ligand while searching the potential binding pose of the ligand in the target cavity. Predicting target receptor structural rearrangements during ligand binding is a complex problem. Unfortunately, docking tools have limited ability to follow the exact modeling of flexibility available to the protein during the binding process (Teodoro and Kavraki, 2003). This problem can be solved by MD simulations although it needs to be remembered that MD simulations are computationally expensive.

Studies comparing different docking tools on a large test set, reported 30% to 80% success rate (Cross *et al.*, 2009; Lape *et al.*, 2010). Modifying basic parameters in the docking software can drastically affect the docking and virtual screening results, indicating that expert knowledge is critical for optimizing the accuracy of docking predictions. Particular docking tool works best for specific targets, it is possible to use multiple docking tools and scoring functions in order to enhance accuracy (Charifson *et al.*, 1999). A universal docking tool (algorithm and scoring function) is not available at this time.

Illustrative Example or Case Study

Plasmodium Falciparum Plasmepsin-II Case Study

Malaria is a widespread problem estimated to kill about two million people each year (Fidock, 2010). Malaria is caused by a protozoan parasite which belongs to the genus *Plasmodium*. Despite considerable progress, researchers are yet to develop a vaccine to prevent malaria. Meanwhile, the emergence of anti-malarial drug resistance has become a major problem, particularly in Africa and south-east Asia (Murray *et al.*, 2012). Development of resistance to artemisinin derivatives and the majority of the potential partner drugs has contributed to the failures of Artemisinin-based combination treatment (ACT), recommended by World Health Organization as the current cure for malaria (Ariey *et al.*, 2014). Apart from drug resistance, other current drug issues such as poor efficacy, toxicity and high production cost also hamper malaria control.

Several targets play a vital role in the survival of *P. falciparum* in human blood stages. Hemoglobin (Hb) metabolism is a critical process during the parasite's life cycle as it provides the main source of amino acids for the growth and maturation of the parasite (Francis *et al.*, 1997). Plasmepsins (PM) are a class of enzymes that play a key role in the degradation of host hemoglobin and have been validated as potential malaria drug targets (Ersmark *et al.*, 2006). The active site cleft of PM II is different from its human ortholog, therefore, selective inhibition is possible. Moreover, PM II appears to be indispensable for parasite survival. It has been shown that PM inhibitors induce malaria parasite death both in culture and in animal models (Ersmark *et al.*, 2006). To date, several peptidic and non-peptidic inhibitors of PM II have been identified including molecules with the statin-based core (Fig. 2). However, most of these exhibits low bioavailability and are difficult to synthesize. The availability of the X-ray crystal structure of PM II makes these enzymes a useful choice for illustrating the process of structure-based drug design to discover novel anti-malarial compounds.

Three different ligand binding modes of *P. falciparum* PM II viz. 'close', 'partially open' and 'open' were described by Luksch *et al.* in 2008 based on the extent of coverage of the flap region on the binding pocket (Luksch *et al.*, 2008) (Fig. 3).

The flap region in the first group folds on the inhibitors and puts the binding pocket in the closed state (e.g., 1XE5, 1M43, 1SME). In the second group, the binding pocket is in partially open conformation (e.g., 1LEE, 1LF2, 1LF3) whereas in the third group the binding pocket is wide open due to the movement of flap lid away from the pocket (e.g., 2BJU, 2IGX). However, since then several new structures have become available in PDB which prompted us to re-look at the data. To classify the new structures, RMSD values from the structural alignment of all the available PM II inhibitor were calculated, which was later used to build a dendrogram for clustering new structures (Fig. 4).

The RMSD dendrogram confirms the three ligand-binding modes of PM II and classifies all the available PM II structures into the close, open or partially open groups. Out of all the structures available in open conformation, a high-resolution crystal structure of 2BJU was selected to demonstrate the principle of SBDD.

Materials and Methods

UCSF DOCK v6.7 (also referred to as DOCK) (Allen *et al.*, 2015) and AutoDock Vina (also referred to as VINA) (Trott and Olson, 2010) docking programs were used in this study. UCSF Chimera (Pettersen *et al.*, 2004) was used to visualize and prepare the receptor structure. A molecular format conversion program called OpenBabel (O'Boyle *et al.*, 2011) and ChemAxon tools

Fig. 2 Known inhibitors of *Plasmodium falciparum* Plasmepsin II.

(ChemAxon – Software for Chemistry and Biology, 2017) were used to prepare ligands for virtual screening and docking. The preparation of receptor files and the determination of the grid box were carried out using AutoDock Tools version 1.5.4.

Receptor preparation

The crystal structure of *P. falciparum* Plasmepsin, 2BJU, in complex with a potent inhibitor IH4 (IC₅₀: 34 nM) was retrieved from PDB. The bound water molecules were removed. The incomplete side chains were replaced using Dunbrack rotamer library (Dunbrack and Karplus, 1993) and the charges on the ionizable residues were made consistent with the acidic conditions found in food vacuoles (pH 5). Subsequently, Dock Prep tool in UCSF Chimera was used to complete the initial receptor preparation.

Fig. 3 Three different ligand binding conformations (closed, open and partially open) of *Plasmodium falciparum* Plasmeprin II described in the literature.

Fig. 4 Dendrogram based on RMSD calculated by structurally aligning all available *Plasmodium falciparum* Plasmeprin II structures in PDB. Structures belonging to closed and open or partially open conformations of Plasmeprin II clearly separate in distinct groups.

UCSF DOCK

After the initial preparation of the receptor, DOCK specific steps were implemented prior to virtual screening as described in DOCK manual. The first step was to calculate the solvent accessible surface area of the receptor without hydrogen atoms using a probe radius of 1.4 Å. The negative image of the surface was created by overlapping spheres using SPHGEN program. The final cluster used for docking had 44 spheres. The binding site was defined comprising all the atoms within the area of 8 Å of the co-crystallized ligand. The definition of the active site covered the catalytic dyad ASP 34 and ASP 214, along with other residues of known relevance. Subsequently, the box was constructed around the active site using SHOWBOX program and the grids were calculated using an accessory program called GRID using default parameters to complete receptor preparation.

AutoDock VINA

For VINA, the receptor PDB files were converted to PDBQT format using `prepare_receptor4.py` in MGL Tools (version 1.5.4). The default box size was calculated following the protocol mentioned by the authors of VINA (Trott and Olson, 2010). Briefly, an

initial docking box is generated based on the coordinates of the native ligand and the box dimensions are increased by 10 Å. If the box size in any dimension is smaller than 22.5 Å, it is extended to this value on all sides.

Library preparation

Around 4.5 million compounds were downloaded from the “lead-like” subset of the ZINC database (Irwin *et al.*, 2012). The dataset was cleaned by applying a number of filters to remove duplicate compounds, incorrect valence compounds and compounds violating Rule of five (Ro5). This step removed over a million compounds. The overall methodology followed for library preparation and molecular docking is shown in Fig. 5.

Next, compounds with sub-structural features commonly found in Pan Assay Interference Compounds (PAINS) were also filtered out using SMARTS strings inspired from the original Sybyl Line Notation patterns provided in the reference (Baell and Holloway, 2010). This resulted in the removal of 111,305 compounds. Additionally, the dataset was screened for potentially reactive and promiscuous compounds described by a set of 275 medicinal chemistry rules, developed at Lilly over a period of 18 years (Bruns and Watson, 2012). Reasons for rejection include reactivity, interference with assay measurements, instability, lack of

Fig. 5 The overall virtual screening methodology adopted to find novel drug leads against *Plasmodium falciparum* Plasmeprin II.

Fig. 6 Superimposition of the best docked poses of the ligand IH4 on the co-crystallized pose in the binding pocket of 2BJU. The DOCK pose (in yellow color) and the VINA pose (in cyan color) has the positional RMSD of 0.79 Å and 1.18 Å, respectively.

drug-ability and activities that damage proteins, among others. A total of 1,349,716 compounds were removed and leaving 1,864,623 filtered compounds. To ensure chemical diversity, the approximately 1.8 million remaining molecules were clustered using PubChem fingerprints as implemented in the ChemmineR package (Cao *et al.*, 2008). The maximum Tanimoto distance between a compound and the cluster center was set at 0.3. This resulted in the multi-molecule file containing 210,735 molecules which were first protonated for the acidic pH 5 and then minimized using the Ghemical force field. Subsequently, the minimized structures were used as the input to VINA and DOCK for molecular docking analysis.

Results and Discussions

Validation of the Docking Methodology

To access the suitability of the prepared target structure for structure-based drug discovery, a preliminary validation of the docking protocol was carried out by re-docking the IH4 ligand to the prepared 2BJU structure with VINA and DOCK programs. The 3D structure of the crystal ligand was obtained by removing it from protein crystallographic complex. The crystal ligand was docked to the receptor protein and from the list of conformations the pose in which the ligand bound with the maximum number of vander Waal and electrostatic interactions and lowest binding energy was chosen as the top ranked binding pose. The experimental pose of IH4 was reproduced. Fig. 6 shows the superimposition of the docked ligand (IH4) with the crystal structure position. The structure is seen to overlap well with the positional RMSD of 1.18 Å in VINA and 0.79 Å in DOCK.

As both VINA and DOCK softwares were able to reproduce the bound conformation of the co-crystallized ligand, therefore, we considered them suitable for further analysis. Overall, VINA produced better results than DOCK in ranking co-crystallized ligands in open and partially open conformations of PM II (Table 4). However, DOCK was superior in ranking 2BJU and 2IGX ligands (both in open conformation) with positional RMSD of 0.7 Å and 0.8 Å respectively, as compared to VINA with positional RMSD of 1.3 Å and 1.1 Å.

Table 4 Comparison of docking scores and rmsd values calculated by redocking co-crystallized ligands of Plasmeprin II in open and partially open conformations

PDB ID	Ligand ID	IC50	DOCK score	DOCK rmsd	VINA score	VINA rmsd	No. of rotatable bonds
Open conformation							
2BJU	1H4	34 nM	− 87.23	0.7 Å	− 10.8	1.3 Å	14
2IGX	A1T	54 nM	− 90.28	0.8 Å	− 11.5	1.1 Å	14

Fig. 7 Structure of eight novel potential Plasmepsin II inhibitors lead molecules. The predicted binding modes of the molecules by DOCK (cyan) and VINA (pink) in the cavity of Plasmepsin II are depicted.

Structure-Based Virtual Screening

In this study, two different docking programs were used to predict novel ligands with high binding affinity to Plasmepsin II. The final library of 210,735 compounds was screened and compounds were ranked based on the docking score to select molecules that had a score better than the cut-off score of -74.0 for DOCK and -9.1 for VINA. This resulted in a set of 823 and 1525 docked compounds from DOCK and VINA, respectively. Compounds that did not form hydrogen bonds with catalytic residues Asp34 and Asp214 were filtered out for further analysis. Subsequently, 25 common compounds were retained and visualized for binding conformations. Finally, compounds with greater than $2.0 \text{ \AA}$ RMSD between binding conformations predicted by DOCK and VINA were removed resulting in the final set of 8 compounds which are listed in Table 5 and shown in Fig. 7.

Since binding of a ligand produces a conformational change in the protein, we proposed that compounds binding in a similar fashion to the co-crystallized complex (ligand IH4 bound to 2BJU) will have a high probability to inhibit PM II *in vivo*.

Future Directions

Structure-based drug design is a powerful method, especially when combined with combinatorial chemistry and high throughput screening. Where access to large compounds libraries is limited or where HTS fails to produce a viable ligand, structure-based virtual screening continues to gain credibility as an alternative source of initial lead identification. The major developments that have facilitated the rise of SBDD to a place of prominence in drug development are dramatic increase in computational speed and efficiency of docking algorithms, ability to incorporate receptor flexibility information during docking, easily available structural data of proteins and compounds, better understanding of interaction of small molecules in the binding site and more accurate methods for estimating protein-ligand binding free energy. The application of computer-aided drug discovery approaches has been extended in both directions of the drug development pipeline, upstream for target identification and validation and downstream for ADME/T predictions.

In the modern genomic era, there has been a dramatic increase in biological data from gene sequences to structural data of proteins and small molecules. The number of potential new drug targets identified has increased more rapidly than the discovery of new drugs. One of the major challenges is to bring the wealth of structural and bioassay data together in an integrated way to design novel, improved compounds that can be readily synthesized.

Currently, there are over 60 docking tools available, evaluation and comparison of different docking programs and scoring functions is an active area of research. Further, protein flexibility during docking has only been addressed recently and the development of computational methods for protein flexibility is still in its infancy and is thereby one of the major future directions (Lill, 2011).

Closing Remarks

This article should provide the reader with an overall perspective of the field of structure-based drug discovery. We have listed and summarized several cheminformatics tools and databases with a special emphasis on software packages that are freely available. We have also outlined the major steps involved in the process of rational structure-based drug design, namely target identification, structure determination, binding site prediction, receptor and compound library preparation, molecular docking, virtual screening and binding free energy calculation. Subsequently, we have applied different SDBB approaches to predict novel leads for hemoglobin degrading enzyme of *Plasmodium falciparum* viz. Plasmepsin II. In addition, we 1) compared the performance of two different docking tools on the Plasmepsin II inhibitor dataset and 2) demonstrated the use of consensus docking methodology for virtual screening of novel PM II inhibitors.

In conclusion, computer-aided drug discovery approaches like ligand- or structure-based pharmacophore modeling and VS can successfully complement their wet-lab counterparts to expedite the drug discovery process. Although computer-aided approaches hold a great promise, it is an evolving technology and still has some shortcomings that should be remembered. The major challenges in the field are 1) to determine the structure of the target, 2) identify suitable hits, 3) progress rapidly to a molecule with the desired activity that does not fail during development and 4) ability to design novel patentable chemical compounds that are easy to synthesize. Finally, *in vitro* testing of the discovered lead molecules is necessary for further optimization of the leads.

Biographical Sketch

Varun Khanna is a research scientist at Vaxine Pty Ltd, a biotechnology company involved in vaccine design. He completed his PhD in Cheminformatics from Macquarie University, Sydney, Australia in 2011. During his PhD he analyzed physicochemical properties, occurrence and co-occurrence patterns of molecular fragments in pharmaceutically important chemical compounds for advancing the knowledge of computational library design in drug discovery. He then moved to University of California, Riverside, USA as a post-doc where he was involved in the chemogenomics, data mining project aimed at carrying out a comprehensive selectivity-centric analysis of ligand-target interactions in public activity profile databases such as PubChem Bioassay. His current research interest includes developing novel techniques for computational drug design, immuno-informatics, fragment-based virtual screening, machine learning and reverse vaccinology. He has authored several research papers in international peer-reviewed journals and two book chapters.

Shoba Ranganathan holds a Chair in Bioinformatics at Macquarie University since 2004. She has held research and academic positions in India, USA, Singapore and Australia as well as a consultancy in industry. Shoba's research addresses several key areas of bioinformatics to understand biological systems using computational approaches. Her group has achieved both experience and expertise in different aspects of computational biology, ranging from metabolites and small molecules to biochemical networks, pathway analysis and computational systems biology. She has authored as well as edited several books in as well as contributed several articles to Springer's Encyclopedia of Systems Biology. She is currently the Editor-in-Chief of Elsevier's Encyclopedia of Bioinformatics and Computational Biology as well as the Bioinformatics Section Editor for Elsevier's Reference Module in Life Sciences.

Nikolai Petrovsky is a Professor in the School of Medicine at Flinders University, Director of Endocrinology at Flinders Medical Center and the founder of Vaxine Pty Ltd, a biotechnology company involved in vaccine design. His research interests including vaccine design, adjuvants, immuno-informatics, and autoimmunity. He has been a principal investigator on multiple grants from National Institutes of Health and has won prestigious awards including the Ernst & Young Entrepreneur of the Year Award and a Biopharma Asian Executive of the Year Award. He has taken vaccines for seasonal and pandemic influenza, hepatitis B and insect sting allergy from the bench to human clinical trials and authored over 140 research papers.

Chemoinformatics: From Chemical Art to Chemistry in Silico

Jaroslav Polanski, University of Silesia Institute of Chemistry, Katowice, Poland

© 2019 Elsevier Inc. All rights reserved.

Introduction

Chemoinformatics (cheminformatics) a term associating chemistry and informatics (computer science) on the lexical level describes a discipline organizing and coordinating the application of computers in chemistry. However, some branches of computational chemistry usually are not included in the field, although they depend on computers. The example here is quantum chemistry which is more frequently insisted to be a part of theoretical physics than cheminformatics because, in principle, it is just the physics of atoms and mathematics that allow the correct modeling of molecular objects, and pure mathematics, hypothetically, can be done without computers (Polanski, 2009b). However, the larger the molecules, the more remote and inaccessible the precise mathematical model. The history of fundamental concepts or theories in chemistry illustrates the complexity of chemical researches. Consider chemical bonding. The molecular orbitals or valence bonding theories describe atomic scale aggregation into molecules. Both models have been competing with each other and chemists still discuss which is correct and which is better. In physics, it is possible to develop a relatively simple model to explain certain facts of nature. In contrast, in chemistry, a theory often partially interprets some data, also offering partial solutions. Thus, we need several high-quality models for the correct theory (Brock, 1993). Theoretical chemistry is an empirical science based on the Schrödinger equation; however, we are aware that its general solution will not be available. In science we use mathematics for modeling and developing theories. In the language of informatics this means mathematics is a compression tool unifying the facts of nature. Now we do not need individual facts any longer. Details disappear and information is coded into a form of a model (occasionally a single equation) that explains the reality. Compressing the complexity of natural information to such models is used typically for an approach called reductionism (Cohen and Stewart, 1994). What if, the Nature appears too complex for an accurate mathematical description or the developed model does not have a precise solution. The answers could be still important but unavailable by precise mathematics. In such situations, we need further substantial simplifications, even in cost of reliability. This brings into the game speculation or educated guess which are still better than blind guess or no answer. Chemists discovered that “educated guess is being supported by the computer” (Kowalski and Bender, 1975). This describes the first application of computers in chemistry, which is to assist a chemist in a calculation or computation that requires the calculation or simulation by computers. Why can computations still be possible, flexible, and efficient in data processing when human calculations fail? The efficiency of *in silico* mathematics is first of all, not by computer intuition or flexibility but by a brute force under relatively simple mathematical formalism (Audibert, 2013; Bock and Goode, 2002). The methods played in computers are evidently different than those involving human brain. Coupling human intelligence with the speed and competence in low-level manipulations observed in computer appeared efficient enough to solve “formerly intractable problems, and explore areas beyond the reach of human calculation” (Audibert, 2013; Jager and Krebs, 2003). Accordingly, the domain of cheminformatics can be preferentially outlined by calculations that cannot do without mathematics in *in silico*, or in other words, those chemistry branches that process massive or ill-defined and fuzzy data for which standard mathematical modeling is unavailable. It was suggested that, chemistry branches that “generate more numbers than information, e.g., physical and chemical property calculation” are not in cheminformatics (Oprea, 2003). It seems however that even though the calculations in the latter case can be performed efficiently in *in silico*, hypothetically, they can do completely without computer assistance basing on the relatively simple mathematics.

The Scope of Cheminformatics

Imitation or simulation of natural systems by building physical or virtual models is a core of scientific method. Basically, cheminformatics is a tool for chemistry simulation in computer. Recent definitions: *using informatics method to solve chemical problems* (Gasteiger and Engel, 2004) or just *in silico chemistry* (Polanski, 2009b) well define the objectives and the scope of the discipline. A term cheminformatics has been coined in the late 90', when computer applications in chemistry had been already controlled by chemometrics, another discipline which associates chemistry and informatics. At the same time chemists were already aware of the potential of computer applications in advanced molecular problems at the same time however also realized that such problems as drug (molecular) design will not proceed as smooth as previously expected. The experience that chemists gained here quenched the early enthusiasm. We understood far more advanced methods would be needed for the efficient *in silico* chemistry. At the same time chemometrics which developed from analytical chemistry only partially cover molecular problems. Therefore, cheminformatics originated as a result of early disappointment of computer assisted drug design as a discipline conceived for “the combination of all the information resources that a scientist needs to optimize the properties of a ligand to become a drug” (Brown, 1998). In Fig. 1 we briefly illustrated the scope of chemical investigations performed in computer in the association with other disciplines. Eventually, a new drug is not only biophysics, but also economic market with its unpredictable behavior. Therefore, the scope of cheminformatics is broad, extending from physics to economy. The large scope decides the complexity of problems is enormous high. In turn, high complexity implies low precision. This fact explains the

Fig. 1 A precision and complexity in chemoinformatics which scope extends from physics to economy.

autonomous character of chemoinformatics which had to develop their own methodology to trigger the computer to zoom on chemical problems recognizing specific chemical patterns and replying to them accordingly. The history of the computer chemistry can be found in Polanski (2009b), Noordik (2004), Polanski and Gasteiger (2016).

Teaching Computers Chemistry: From Molecular Data to Chemical Information and Chemical Ontology

The development of technology, in particular, scientific equipment capable of describing human environment by any type of records provided us with data, where data can be interpreted in the broadest sense as anything that is recorded, including metadata, i.e., data referring to other data. This can be both ordered and unordered collections of both nominal and numerical values, whereas the latter can be discrete numbers, intervals or ratios. Another type of data (binary large objects, BLOBs) is used to describe audio, video and graphic files (Maheshwari, 2014). With the enormous increase of data volume the so-called big data appeared recently. It is generally believed that big data brings new value and innovation. For example, Szlezak *et al.* cited the recent McKinsey research that suggests that the potential use of big data in US health care could reduce costs by \$300 billion a year (Szlezak *et al.*, 2014). Current impact of big data for drug design is however far less noticeable that could be expected. The reason is that, first, this kind of information is much less clearly defined and messy. Accordingly, its analysis causes serious problems. Second, 120 million compounds were synthesized and registered in databases; however, this should be compared to 7 billion individuals in human society. Data gets bigger while going from chemistry to biology or economy (where humans are interacting). A single genome for a single individual can be interpreted as special type “big data”, e.g., already a structure of the genome is a large record. A phenotype yielded by the genome is a specific property. In comparison, a population of drugs or bioactive molecules is represented by much smaller data, in particular measured properties. Therefore, the generation of big data here must go by the increase of the number of properties registered for a single molecule, e.g., polypharmacology. Third, the availability of big data for drugs is limited because of the need to keep the secret during drug development. Therefore, in order to replace such data a library of building blocks is analyzed to probe big data behavior of the large molecular populations (Polanski *et al.*, 2016). Formal classifications of big data and their analyses were discussed in Polanski (2017).

Science, in particular, chemistry is knowledge organized from data, that is, facts and numbers making up information. In turn, information develops chemical knowledge. Atoms, molecules, substances and their properties and transformations are the main objectives of chemistry. An unbelievably large number of molecules can be arranged from a matter available in the universe. The efficient data storage and management is needed for the control of this molecular representation, which indicates the next field of computer application in chemistry. Generally, a structure of chemical information is often chaotic which prevents its obvious transformation to in silico form. This can be illustrated by a fact that chemists often underline chemistry is an art. This means that a human expert is needed for the efficient playing with uncertainty in the field. In turn, computer is an unsophisticated *device* for which uncertainty is a problem. Therefore, computer-understandable chemistry needed to be developed to store and process chemical data and information. Translating molecular data into a machine-readable and -processable structure is far from triviality. A problem is also the interaction between chemist and computer.

Chemical compounds (CC) are the main objects of chemical investigations. Surprisingly, although commonly used in chemistry a term chemical compound has never been defined by IUPAC. Historically, the ambiguity of the term CC can be related to the early term of *mixts*, a result of *mixing different bodies* (not necessarily in the contemporary chemical sense). Mixts was replaced in 18th century by composition or compounds (Bensaude-Vincent and Simon, 2012). What originally related to substances can be however also associated with molecules which are the combinations of chemical elements. Therefore, CC refers both to molecules and substances (chemical species). Actually, the meaning of the term CC is intuitively interpreted by a chemist and can indicate (Polanski and Gasteiger, 2016):

- A *synonym of a molecule* (composed of at least two different atoms) representing a single chemical body for virtual needs (coding, in silico processing, visualization, etc.)
- A *molecule* representing a single chemical body under measurement (e.g., a single DNA strand that can be observed, e.g., under microscopy).

- A *substance* composed of a replicated but single molecular entity under measurement.
- A *chemical species* under measurement when replicated is more than one molecule type.

However, a simplified meaning of a molecule is also a model-like representation that can refer both to a chemical compound that has been yet synthesized and described, or to a virtual structure (hypothetical compound) that is under design or speculation. Historical reasons decide that molecules belong to the domain of organic or inorganic chemistry. Although the organic vs. inorganic typology is more and more fuzzy the proportions of chemical compounds are approximately 1:200 in favor of organic chemistry, if we follow standard rules. The management of chemical compounds needs the efficient machine-searchable databases registering all virtual structures and real compounds that have been synthesized and described in chemical literature from the very early days to today. This problem of substantial importance for the organization of chemistry in silico is known under the term *structure representation and searching* (Willet, 2003) which basic concepts has been formulated as early as 1960s. Atomic composition given by molecular formulae is not sufficient to unambiguously identify a molecule. Therefore, in the broadest sense the structure of the chemical entity is defined by constitution and stereochemistry. What we mean by constitution is “the description of the identity and connectivity (and corresponding bond multiplicities) of the atoms in a molecular entity (omitting any distinction arising from their spatial arrangement, i.e., molecular stereochemistry)”. Isomers are chemical entities of the same atomic composition but different constitution and/or stereochemistry or precisely isomers are “one of several species (or molecular entities) that have the same atomic composition (molecular formulae) but different line formulae or different stereochemical formulae and hence different physical and/or chemical properties.” In particular, a line formula is an example of molecular representation showing atoms that are “joined by lines representing single or multiple bonds, without any indication or implication concerning the spatial direction of bonds.”

We more and more understand in chemistry the importance of the precise shape of chemical formalism, typical for mathematics and physics. However, at the same time we would like to preserve the completeness of chemical information with its uncertainty. Therefore, we need an intelligent in silico system fitted to receive the *soft* chemical data without information reduction or deterioration. In this context *chemical ontology* is a recent solution of this problem (Hastings *et al.*, 2011). It is a flexible dictionary like chemistry representation, a system capable of organizing the complete chemical information in silico. In other words, the strategy here is that the chaotic nature of chemical information is tamed not by the significant information reduction but by building a structure capable of accepting all variety of data and facts. The inspiration for the chemical ontology seems to be object-oriented programming where a processing of information attempts to imitate reality. We are defining here not only the data type of a data structure, but also the types of operations or functions that can be applied to the data structure. Therefore, data are structured by objects that includes both data and functions. Furthermore, relationships between the objects are defined. In particular a category of class is an extensible program-code-template for creating objects, providing initial values for state (member variables) and implementations of behavior (member functions or methods). Accordingly, let focus on chemical compound which can be defined as a class having a fixed ratio of defined atoms and a chemical structure that can be expressed by one connection table of non/hydrogen atoms and one or more connection tables that include hydrogen atoms and bond orders as well, connected by OR logic. This allows, for example, to clearly classified all tautomeric forms of vitamin C as a single chemical compound (Bobach *et al.*, 2012).

Between Descriptors and Properties

Basically, chemical compounds can be represented by descriptors or properties, whereas a property is to be measured in experiment and a descriptor is calculated or more precisely is a final result of a logic and mathematical procedure transforming chemical information encoded within a symbolic representation of a molecule into a useful number (Todeschini and Consonni, 2000). As in real world we usually have a contact with substances the properties will mainly refer to the substances, while descriptors to the molecules. However, this is not always true because we can also measure the property of a single molecule, e.g., MW in the MS spectrometer like conditions. A fully consistent differentiation between properties and descriptors could not always be easy. Interestingly, while IUPAC identifies only properties (descriptors are also classified as properties); in chemoinformatics all parameters are often referred to as descriptors. Properties are recorded here as physicochemical descriptors, e.g., molecular descriptors are divided into two main classes: experimental measurements, such as log P, molar refractivity, dipole moment, polarizability, and, in general, physicochemical properties, and theoretical molecular descriptors” (Consonni and Todeschini, 2010). In turn Polanski and Gasteiger argued for a clear and consistent descriptors versus properties differentiation (Polanski and Gasteiger, 2016). It has been shown recently how important and informative this taxonomy can appear (Polanski *et al.*, 2016; Polanski and Tkocz, 2017). Accordingly it has been demonstrated that *ligand efficiency* (LE), a molecular descriptor designed for an early evaluation of drug candidates (Hopkins *et al.*, 2014); if interpreted not as a descriptor but as statistical property allows to explain an evident preference of small ligands. Actually, LE does not characterize a real binding potency but is related to the statistics involved in the binding of the 1 g sample of the ligands (Polanski and Tkocz, 2017). This indicated the next difference between descriptor which can be clearly related to a single molecule and a property of the substance which can also be a statistical parameter not so obviously connected to a single molecule.

From Problems to Concepts

In the previous articles we illustrate the difficulties of the adaptation of chemistry to an in silico method. A variety of terms that are interpreted by human chemists intuitively are not well suited for computers. This should have been first understood well enough

to be transferred to a form understandable for computers. Structure representation is an example of the early problem that should have been solved to teach computers chemistry. We briefly presented the examples of the molecular problems and in silico concepts to deal with them after (Polanski and Gasteiger, 2016).

Problems

- *Chemical data documentation and searches*: database searches and management
- *Calculating molecular descriptors*: 2D (chemical graphs) and 3D (molecular modeling) representations are mapped into single numbers (0D); vectors, fingerprints (1D); matrixes, surface maps (2D); surface, atomic representations, force fields, virtual or real receptor data (3D); etc.
- *Molecular modeling*: molecular structure 3D data generation in silico from their 2D or 1D representations. This includes both predictions of molecular topography and molecular descriptors i.e., atomic annotations data by calculated (simulated) atomic properties.
- *Structure elucidation*: (synonym: structure-spectra correlations) property to molecular structure is mapped in factual chemical space (FCS) when we are attempting to find a structure having a certain spectra or in structure to property version we are simulating a spectra for a given molecule (substance).
- *Mapping structure to activity* (SAR): a series of structures (FCS substances) is needed to study SAR, which are usually synthesized. The real goal of SAR is usually to predict the training series for designing new structures and substances by property predictions in a qualitative or quantitative procedures.
- *Property prediction*: compounds' series (FCS) are mapped from FCS into virtual chemical space (VCS); two basic versions are available, i.e., property vs. property or structure vs. property. However, in the design step for novel compounds in VCS (we can design both compounds VCS or FCS where some properties can be registered in databases and/or literature) we are always to use a structure version (no property is available in VCS).

More Important Concepts

- chemical space (CS), factual CS (FCS) or virtual CS (VCS) SMILES coding
- connectivity (graph theory) approaches, additivity concept, molecular modeling, force fields
- molecular mechanics, molecular dynamics, force field, molecular interaction field, partial atomic charges, lipophilic potential
- RDF structure coding (2D), 2D structure–2D spectra correlation
- SAR, QSAR, QSAR domain, similarity measures, privileged structures, fragonomics
- QSAR, QPAR, log*P* versus partition coefficient, fragonomics, virtual screening
- Synthons, retrosynthetic analysis, synthesis tree

Some of them are adopted directly from chemistry where they originated not necessarily with a thought of computer applications. For some others in silico methods were an obvious inspiration.

Chemical Space: From Storing Information to Advanced Ontology Formalism

The population of chemical data has significantly increased in recent years. In particular, Chemical Abstracts Service (CAS) has registered almost 130 million unique organic and inorganic chemical substances, 67 million sequences. The daily update records 15,000 substances. Substance information, includes both molecular descriptors, property and predicted property data includes more than 7.6 billion property values, data tags and spectra. CASREACT contains 83.6 million single and multistep reaction data entries. The Pubchem BioAssay Database records count to millions (Wang *et al.*, 2017). The number of potential compounds, i.e., the population of chemical space is however much higher. This number is estimated between 10^{18} and 10^{200} , whereas 10^{60} is probably the most representative value found in the literature. We can compare this to the factual CS of the order of $10^7/10^8$. Alternatively, a number of stars in the universe is estimated to 10^{22} (Polanski and Gasteiger, 2016; Baldi, 2005; Bohacek *et al.*, 1996). The enormous population of CS can be realized better if we evaluate the potential expansion of *n*-hexane into a family of analogues decorated with 150 different substituents. Accordingly, if we bring together a full collection of mono- to 14-substituted analogues count to a population of 10^{29} (Lipinski and Hopkins, 2004). Therefore, chemical synthesis or the construction of new chemical molecules cannot do without a well-organized data mining system that allows us for a verification of physical and/or chemical data by screening a large population of the variety of compounds described. This problem is fundamental for chemistry, where the access to information is a common need. Moreover we would like to have proper data delivered at the proper time to the chemist's desk. An efficient chemical information system on chemical compounds needed to be developed from the very beginning of chemical investigations. Actually, *Chemisches Zentralblatt* appeared as early as 1830; while the first edition of Beilstein's *Handbuch der Organischen Chemie* (BH) was published in 1881. Even in that time the latter contained two volumes, registering 1500 compounds, with more than 2000 pages. In chemistry we realized quite early that the improvement in data storage could be of the crucial importance for the development of chemical sciences. However, searching a compound within thousands of pages of the printed book was tedious and impractical. Instead, the computer desktop could provide an

efficient environment for the management of chemical data and chemistry could evidently profit from computers. Accordingly, chemical information is a core component of chemoinformatics.

This means that we need new tools for storing and manipulating chemical data. *Chemical space* (CS) is an example of the idea that contributes not only into the computations but also to the chemical documentation. The original CS concept was inspired by the cosmological universe populated by stars, where chemical compounds replace cosmological objects to navigate chemical space (Lipinski and Hopkins, 2004). The vague cosmological analogy can be replaced by more precise parallels. Accordingly, mathematical model was designed. Practically, clear illustration of the chemical operations by in vitro and in silico operators appeared to be the most important functionality in this method (Polanski, 2009b; Polanski and Gasteiger, 2016). Summing up CS is a concept which appeared in the hope of organizing a whole population of chemical compounds. Essentially, CS is a structure for the mapping of chemical compounds by descriptors and properties. Furthermore, potential operations schemes accompany crude data. If we realize these functionalities we can easily understand that in the current chemoinformatics *chemical ontology* is an advanced formal structure that represents a CS system for in silico chemistry that allows for a flexible multipurpose property and descriptor registering and manipulation in silico. Ontologies encode human knowledge in computationally accessible forms. They are designed to narrow the gap between the knowledge of human experts and the functionality available in computer systems, by expressing expert knowledge in a manner computers can manipulate and reason over (Hastings et al., 2011).

Basic In Silico Functionalities

Coding Chemical Information Into Molecular Descriptors

Molecular graphs encode chemical information that can be transformed to a variety of useful numbers, or in other words molecular descriptors (Todeschini and Consonni, 2000). A variety of molecular descriptors, their taxonomy and detailed algorithms or software for their calculations from molecular representation are available nowadays. This decides that usually a large number of calculated molecular descriptors are accompanied by few measured property data. This effect described as a property deficit (Polanski and Gasteiger, 2016; Polanski, 2017) results from a fact that the measurements are much more expensive than in silico calculations. On the other side this illustrates the success of in silico chemistry.

Computer-Processable Molecular Codes

Two-dimensional atom arrangement of chemical entities can be coded into molecular graphs which are easy-to-read for chemists; however, are not computer-friendly. Accordingly, we need a method for a proper translation of molecular graphs to a form that would be understandable for a computer system. Coding molecular graphs by linear notation or connection table forms a typical computer representation. In the linear notation a molecule is represented by a string of the line formulae type. An example of SMILES (Simplified Molecular Input Line Entry) notation can be an up-to-date illustration of such a system (Weininger, 2003). The detailed tutorial can be found online in the Daylight Chemical Information Systems. Matrix representation is an alternative for coding chemical graphs. The examples here are adjacency matrix, atom connectivity matrix, incidence matrix, bond electron matrix. Molecular structures can also be coded by connection tables which record atoms and bonds within a molecule. The need of the individual application decides a form of the computer representation that we use. An in-depth description of the matrix and connection table codes can be found in the Handbook of Chemoinformatics edited by Gasteiger (2003). A precise definition of chemical compound could need a combination of connection tables, which can be achieved by the chemical ontology method.

A connection table or linear notation can be formed arbitrarily. This means that numbers can be assigned to the atoms differently and there is none standard molecular representation. Canonical labeling is a solution for this problem. This provides a unique representation for a certain molecular graph. Unique SMILES are example of such canonical labeling system (Daylight Chemical Information System). Chirality is an important chemical structure property and ISOMERIC SMILES is a system allowing for various chiral and isotopic specifications.

Molecular Editors

Molecular graphs are unambiguous, chemist friendly and illustrative way for the presentation of molecules constitution and stereochemistry. Molecular editor is an interface that allows a user not only to draw professionally presented molecular structures but it is also a tool for the translation of such a structure into the computer processable molecular codes. A number of systems have been developed that are capable of the translation of molecular formulas introduced into computer by its user in a form of direct drawing, e.g., using a mouse, to the machine readable code. ISIS, ChemSketch ACDLAB, JME, RasMol are molecular editors available free of charge at the web sites, respectively (Polanski, 2009b).

Coding Chemical Reactions

Chemical reaction refers to a dynamic behavior involving both a breaking and formation of chemical bonds, in which chemical compounds are transformed from reagents to products. Accordingly, chemical reaction changes the atom bonding system in molecules. The problems encountered while naming chemical reactions resemble those that are typical in the nomenclature of chemical

Fig. 2 Reaction coded by the $B + R = E$ matrix. Reproduced from Gasteiger, J., Engel, T., 2004. Chemoinformatics: A Textbook. Weinheim: Wiley-VCH, p. 186.

compounds. For example common reaction nomenclature often honors distinguished chemists, the discoverers of the certain reactions. This remind us the trivial chemical compounds nomenclature, because trivial name encodes no information on the reaction itself. Merck Index can serve as a dictionary guiding us through the name reaction chemistry (Smith *et al.*, 2001). An online alternative is the name reaction database of the Organic Chemistry Portal (Organic Chemistry Portal). Similarly to the nomenclature of chemical compounds IUPAC developed a systematic reaction classification capable of coding a variety of useful information on the molecular transformation; however, this is used only very seldom (Polanski, 2009b). Molecular transformations in silico can be coded by an algebraic model based on logical connectivity and matrix equation $B + R = E$, where B (beginning) represents an initial reaction stage, E (end) codes a final state and R is a reaction matrix. Fig. 2 illustrates an example of the reaction noted in such an approach (Gasteiger and Engel, 2004).

Other representations and classifications of chemical reaction, including SMARTS, has been developed but will not be discussed here further and a reader is referred to the references available in Gasteiger and Engel (2004), Chen (2003) or at the internet site of the Daylight Chemical Information System.

Organizing Chemical Facts Into Databases

Finally, what we need to enable chemists using computers to perform efficient chemistry is the access to chemical information, i.e., chemical data represented by chemical facts and numbers. Thus, for example, coding chemical transformation as described in section "Coding Chemical Reactions" does not bring information on this specific reaction gathered by experimental chemistry which are often fundamental for the chemists. Therefore, the additional data on the reaction conditions, solvents, temperatures, catalysts or byproducts have to be shaped to a form compatible with the computer platform. Accordingly, organizing chemical data in searchable databases is a focal point. A variety of chemical databases are available on-line having user-friendly interfaces. This includes chemical reaction or substances databases as Reaxys (formerly Beilstein) or Chemical Abstracts, patent databases as esp@cenet, chemical substance catalogues, e.g., Aldrich, or on-line chemical journals.

Managing interactions between a chemist and computer needs chemical information and software which puts together to a chemoinformatic platform capable of understanding chemical data efficiently assisting computer-aided chemistry or advising chemists in more traditional chemistry branches. Below we discussed some of typical problems of data processing and data output.

Computer Generated Chemical Names

Chemical structures can be nowadays easily transformed to chemical names. Chemical name generators typically are supported by a molecular editor. Historically, Beilstein pioneered in this field with the AutoNom program, which succeeded in 86.3%, if tested for more than 63,000 structures. Currently, AutoNom can generate both Beilstein or ACS nomenclature forms. Alternative software has been developed by Advanced Chemistry Development Inc. The ChemSketch freeware is a part of the extensive platform available at the ACD/Labs internet site (ACD Lab). Coding name generator was discussed in the Wisniewski (2003).

Molecular Modeling

Basically, what we mean by molecular modeling is simulating molecular structures in silico. This involves molecular manipulations such as visualizing, merging, superimposing or rotating individual molecules in space but also rotating bonds within individual molecules, etc.

More generally, molecular modeling involves the predictions of various molecular behaviors and properties. In particular, this includes predicting molecular shape, e.g., by 3D structure generation, simulation of chemical or biological effects. Modeling virtual molecular structures is not a trivial problem and includes a variety of computational schemes on the different level of approximation (Holtje *et al.*, 2003). The importance of molecular modeling can be understood better if we realized that chemistry often needs to investigate virtual or hypothetical structures, for example, active complexes that would be extremely unstable or even could have never been synthesized. In such cases a single possibility offering 3D molecular representation is computer modeling.

2D and 3D Structure Generators

Current methods often demand to analyze thousands or even millions of structures. Obviously, this cannot be realized by any system operated manually. Instead, we need the automated algorithms. Actually, nowadays this can be easily programmed in a variety of environments. Alternatively, a ready to use databases of virtual compounds are available (Reymond *et al.*, 2010). It is important to realize that chemists usually simplify a real structure of a chemical molecule to its molecular configuration. For example, the shape and stability of E and Z isomers which are two different configuration series are commonly estimated solely on their configuration type, irrespective of the actual 3D structure of the individual molecules. Such simplification is often sufficient, in particular, in organic chemistry where more detailed molecular representation will be even too complex and impractical. However, molecules are three dimensional and we can indicate the exact space location of individual atoms with high resolution. In some areas as medicinal chemistry such high resolution molecular representation can be of substantial importance. Traditionally, we use X-ray diffraction on crystals. However, as this effect is limited to the condensed matter (crystals), many further approaches appeared that allow to disclose various structural data defining 3D structure; however, general technology is still unavailable here. Despite an impressive progress X-ray crystallography is still a tedious process demanding producing crystals. Moreover, we can doubt a full correspondence between atom configuration in condensed matter vs. this in other environments. Accordingly, even nowadays only a small fraction of factual chemical space is described by the respective 3D structures despite a fact that such a data are sought after in particular for peptides or drug–ligand complexes (Motherwell, 2004). In other words 3D structures as measured properties are rare.

The importance of molecular modeling can be illustrated by a variety of descriptors and properties influenced by 3D molecular structure. Shape is an example of molecular descriptor that directly depend upon 3D structure. This is, however, a fuzzy category because molecules are capable of adopting different configurations and/or conformations (representing different shapes), depending upon the requirements of the environment. Accordingly, a population of the available shapes depends on the energy of the molecule. An uncertainty of this category explains a fuzzy nature of the properties and effects of various chemical or biological effects that are controlled by shape. This includes drug-receptor recognition and interactions. All shape effects can be currently modeled in silico (Polanski, 2003).

The generators of 3D structures are designed for a high-speed conversion of 2D into 3D molecular representations. Formally, this will be molecular descriptors, obtained by property prediction. How such descriptors can be calculated? Usually, X-ray structures are a kind of standard for experimental atomic 3D coordinates. 3D structure generators are programmed to use a model atom types for certain hybridizations to calculate standard bond length and bond angles. Typically, the strategy includes additional rules as preferred conformations of ring structures. As the speed and program performance is preferred, non-typical atom input should not crash the software. Instead, reasonable value would be expected.

LHASA is an early example of 3D generator designed to evaluate influence of steric hindrance on the reactivity of cyclohexane conformations. Model builders are another example of the program block capable of generating 3D atomic coordinates in an interactive mode. This allows to convert a molecular graph drew by a user at the program interface into a 3D molecular structure. Typically, the programs use built-in rules for the generation of the approximate structures having standard bond lengths, bond angles, torsion angles and stereochemistry. Usually generated structures require further refinement by geometry optimization. High-speed conversion of 2D to 3D representations of the large molecular populations are the main task of such programs. The examples of the software for automated structure data conversion includes CORINA, Cobra, Alcogen, Chem-X, Molgeo. Obvious priority here is a speed performance which can achieve more than 10^5 small to medium-sized molecules in ca. 2000 s on a 1.0 GHz workstation with a performance of 23 ms/cpd yielding a 99.99% conversion rate for the Corina program (Sadowski and Gasteiger, 1993). Optionally we can generate multiple ring conformers, rotamers or tautomers (ROTATE and STERGEN).

Modeling 3D-structures

Virtual molecular models in silico provides a useful platform widely used in nowadays chemistry. At the same time, theoretical chemistry developed a variety of methods aimed at modeling structure and bonding systems using a various molecular or quantum mechanics approaches which owe their origins to the Born-Oppenheimer (BO) approximation. In particular Schrödinger equation:

$$H\Psi = E\Psi$$

relating the wave function Ψ , Hamiltonian operator H , and energy E terms can be given in a simplified form. Formally, H includes components responsible for nuclear kinetic energy, electron kinetic energy, nuclear repulsion energy, electron repulsion energy, electron-nuclear attraction. In the BO approximation we assume that electron distribution depends on the fixed nuclear position only, which means that nuclear kinetic energy term can be neglected in the H operator. Introductory tutorials to molecular

modeling with representative references are widely available (Holtje *et al.*, 2003). A term *molecular mechanics* (MM) has been coined in 1970'. This refers to a so-called force field method (Hinchliffe, 2003) based on the assumption that a population of atoms in the molecule can be described by the potential energy depending upon the space locations of the atoms. This allows us for the optimization of the molecular geometry. The mechanics needed for the calculations of potential energy have been developed using classical physics. A suggestive model where atoms are balls and bonding are springs connecting the balls are commonly associated with this method in the chemical audience. Analytical functions are used to describe atomic interactions defining the so called force field. A variety of force fields have been developed to adopt the method for the different chemical functionalities and compounds' classes. Illustrative examples are MM+, AMBER, BIO+, OPLS. Via parameterization a force field concept can incorporate electronic energy in MM calculations. The MM method give us an insight into the molecular geometries and energies which minimization provides us the simulated low energy molecular model within the accessible molecular geometry space. Currently, a variety of MM software packages are available, e.g., HYPERCHEM, Sybyl including freeware options, e.g., the Tinker package. Informative tutorial and review of the methods and applications can be found in Goodman (1999), Keseru and Kolossvary (1999). Alternative online materials are offered by Rzepa.

Semiempirical quantum mechanical methods (SM) can be used for further approximation of the molecular models. This provides us with the deeper insight into the electron distribution within a molecule. Various levels of approximation are available in SM for the simulation of molecular orbitals. The calculations involve only valence electrons and are based on a set of experimental parameters forming a database referring to a certain set of chemical compounds. Such a strategy makes the calculations much easier. The examples are the AM1, MNDO, PM3, CNDO or INDO methods (Holtje *et al.*, 2003).

Molecular dynamics (MD) is an approach in which a single point atom location is modified to cover the dynamic atom behavior. In this model a nuclear system goes into a motion under a certain temperature forces. The motion is simulated by the Newtonian dynamic equations which solution indicates the set of possible atom locations. In particular, this allows to determine a so-called conformational ensemble profile for a molecule. Thermodynamic and dynamic properties of the molecules can be calculated using the MD method. The MD appeared especially useful for the simulations or refinement of protein shapes including X-ray structures. For further discussion of MD methods and applications compare Rapaport (2004). Many recent advances involve molecular dynamics simulations of proteins in explicit mixed solvents applied to various problems in protein biophysics and drug discovery including protein folding, protein surface characterization, fragment screening, allostery or druggability assessment (Kimura *et al.*, 2017). AQUA-DUCT: is an example of the up-to-date tool for the identification and tracking of molecules which enter active site cavity among thousands of single molecules along several thousand molecular dynamic steps (Magdziarz *et al.*, 2017).

Structure and Substructure Searches

Comparison is an important method in chemistry. In particular, this includes molecular structures. Therefore, structure or substructure searches is a substantial problem in a variety of the issues discussed in this article. An illustrative example is a need for the registration of novel chemical compounds and reaction within databases. A structure query is the essential operation for which molecular graph has to be translated to a canonical molecular representation. An example of a function that enable data structure organization is the so-called hash key. In turn, hash codes can be obtained from canonical SMILES strings or Augmented Connectivity Molecular Formula, e.g., in ACS Registry System. Additional information and references are available in Leach and Gillet (2003).

Structure query is the most simple database operation. Nowadays substructure search is also a routine. This provides us a method for the identification of the defined molecular fragment included in a series of molecules (Noordik, 2004). Graph theory, in particular the so-called subgraph isomorphism, can provide theoretical framework while practically a binary string molecular representation enables rapid structure screening (Leach and Gillet, 2003). The procedures developed include structural key (Boolean array) representation which can be a bitmap where each element coding a true or false refers to the presence or the absence of a certain structural feature or pattern. Alternatively, high-speed structure queries can involve fingerprint representations. In turn, a concept of molecular similarity measures enables the similarity based searches. For the essentials compare (Kochev *et al.*, 2004). Occasionally, for example, in drug discovery finding a common 3D pattern by mining 3D structure databases is an important problem. Database mining and identifying such a pattern known as a pharmacophore can assist a search for new ligands in the ligand based drug discovery paradigm (Nicklaus, 2003). Software available for the procedures discussed in this article can be found in the Kochev *et al.* (2004). Recently a concept of the so-called chemotype appeared. This represents molecules, chemical substructures and patterns, reaction rules, and reactions. This method is capable of integrating types of information beyond what is possible using current representation methods (e.g., SMARTS patterns) or reaction transformations (e.g., SMIRKS, reaction SMILES). For example new publicly available chemical query language, CSRML, to support chemotype representations for application to data mining and modeling has been developed recently by Yang *et al.* (2015).

Molecular Graphics

Formally, molecular graphics refers to a visualization of molecular objects, but this term is also used as a synonym of molecular modeling. Because molecular objects are complicated solving a chemical problem needs high speed and quality in virtual reality. Therefore, molecular graphics has significantly contributed to the currently available computer visualization technology.

Computer screen has been used for scientific visualization of physical models as early as in 1960s in the MIT during the Mathematics and Computation project. Developing technology for molecular visualization engages both chemistry and computer sciences. Currently, virtual chemistry on screen is a routine and highly interactive user-friendly systems are expected to be a part of each molecular platform. Molecular representations here can range from the atoms to the surfaces including a variety of others symbolic forms (Keil *et al.*, 2003). For a brief discussion on the differences between physical and virtual model compare Morris (2002).

Advanced Functionalities: In Silico Chemistry

Chemical Syntheses and Retro-Syntheses (Disconnections)

Chemical objects can be constructed via chemical synthesis. We can understand the importance of this problem in chemistry if we realize that even today chemical synthesis can be a bottleneck in research and a variety of applications. Chemists still believe chemical synthesis is an art. For the better illustration of this issue let us take a textbook example. Atropine, a natural product available from nightshade or belladonna was isolated and used already in ancient Rome and India. Of course the structure of this compound cannot be identified at that time. A core atropine moiety was proved to be tropinone in 1901 when Willstätter synthesized this compound. This needed however a complex more than 20 step synthesis which resulted in a total yield of no more than 1%. Low yield suggests inefficiency and makes easy to overlook the stunning success of this masterpiece of a synthetic work performed by a nobel prize winner. Even today this project would pose a complex organizational challenge, despite an availability of precise and rapid NMR or MS spectrometers easily and rapidly identifying the structure of compounds synthesized. True excitement comes however with the Robinson approach, Fig. 3. One step condensation and decarboxylation can result in more than 90% yield of tropinone (42% yield was originally reported).

It is still true, that the efficiency of synthesis critically depends on the skills and creativity of chemists. Can computers play a role in synthesis design providing us useful hints and supporting our skills?

The Development of Product to Reagents Strategy in Synthesis Design

Practical applications needs novel substances which are to be designed and produced for the industrial, pharmaceutical, agricultural use. This indicates the importance of a chemical product. Products are formed in chemical reactions; however, products appears at the very end of the process which starts from reagents. Therefore, in order to know how to design the products in a rational way we should have first explored a conversion of a variety of chemical compounds and functionalities. This explains how historical development of the chemical knowledge has imprinted into the organic chemistry textbooks where chemical reactivity of a molecule is a core issue. This decides also chemists are trained in a reagents to product chemistry where products can be designed basically only by a nondirect screening of possible reactions. However, an efficient general solution in such a strategy would need for example a database for the direct searches of products. This however, cannot be realized because a database registering all possible virtual products would be impracticable due to a fact that chemical space is too highly populated. Therefore, for years

Fig. 3 Willstätter (upper) and Robinson (lower) approaches to the tropinone synthesis. Reproduced from Polanski, J., 2009. Chemoinformatics. In: Walczak, B., Tauler, R., Brown, S. (Eds.), *Comprehensive Chemometrics* vol. 4. Amsterdam: Elsevier, pp. 459–505.

Fig. 4 A simple example of the disconnection to an acceptor a^1 and donor d^2 synthon. Reproduced from Polanski, J., 2009. Chemoinformatics. In: Walczak, B., Tauler, R., Brown, S. (Eds.), *Comprehensive Chemometrics* vol. 4. Amsterdam: Elsevier, pp. 459–505.

synthesis design were focused on a reagent to product method using a variety of nondirect approaches which can involve (Barone and Chanon, 2003):

- exploring synthetic availability of a substructure of the target molecule (TM), which can provide the major synthetic step opening the way to target molecule,
- an identification of chemical compound (reagent) similar to the target molecule. This allows to transform synthesis design to a problem of the conversion of the structure of this reagent to the structure of the target molecule,
- an identification of a substructure of the target molecule available as a natural product, if present that can be included as a ready-to-use fragment or so-called building block, e.g., an example can be chiral pool synthesis where building blocks are enantiopure substances.

Eventually, we know a bunch of serendipitous discoveries that provided us with the efficient reagents to product conversions.

A direct product to reagent strategy for designing synthesis has been developed by Corey and Cheng (1989). This allows to start synthesis design from a product, commonly referred as a target molecule (TM) or synthetic target. Operations called retro-synthesis, transform or disconnection identify retron or synthon representation of reagents. The meaning of retron and synthon is very close. Retron means a subunit structural pattern identified in the molecule of product designed as TM, provided that we can discover also a transformation representing (retro-reaction). Synthon represents any group of atom(s) indicated by disconnecting chemical bonds in TM in such a way that we can find real reagents representing these synthons and chemical reactions yielding the product called TM. Synthons are virtual chemical entities. Heterolytic bond disconnection results in the moiety having a potential for the electrophilic or nucleophilic behavior, coded by plus (+) or minus (−) signs indicating the acceptor or donor synthon types, respectively. In Fig. 4 we illustrated a simple example of the disconnection. Instead of clearly indicated virtual synthons in many advanced analyses we can find directly reagents, for example Corey did not use this term in his recent monograph (Corey and Cheng, 1989). Some essentials of synthon chemistry is discussed below. For further details a reader should compare Smit *et al.* (1998).

Synthon Nomenclature

Carbon chains formed of C-C and C-H bonds are the most common motifs in organic compounds. Although some reactions may be possible in such systems, in order to observe useful reactions we usually need to differentiate individual atoms by bonding to chemical elements other than C or H. The resulted reactivity differentiation is called chemoselectivity. For example oxygen or nitrogen if bonded to the carbon atom significantly modifies the reactivity of their chemical neighborhood. Therefore, molecular modules other than C-C and C-H are called functional groups or functionalities (FG). FG are of key importance in the contemporary synthetic chemistry approaches. In particular, the mode in which FG influences the reactivity of the neighboring hydrocarbon plays a role in designing potential chemical reactions of the systems. Accordingly, synthon atoms are numbered in relation to the location of the FG and a disconnected (usually carbon) atom (Fuhrhop and Penzlin, 1983) Fig. 4 illustrates a simple disconnection yielding a common carbonyl acceptor synthon a^1 and carbonyl donor synthon d^2 .

Operations on Synthons

Synthons formed in disconnections are virtual entities that need additional operations in order to indicate a corresponding reagents. Synthon to reagent transformation needs at least an addition of an ending at the terminal atom, but can also be much more complex. The basic assumption of organic chemistry is that a certain FG determines a certain reactivity for a series of chemical compounds, e.g., aldehydes react with alcohols to form acetals. A concept of synthons allows us further generalization. Synthon chemistry indicates the reactivity type, comprising various FGs. Some common operations beyond synthetic procedures includes modifications to control synthon reactivity (in blocking, activating or umpolung, i.e., activity reversal mode). A brief introduction to these topics can be found in Polanski (2009b), Smit *et al.* (1998).

Computer-Assisted Synthesis Design

Total synthesis is a term that describes a synthesis yielding natural products. Mimicking Nature and designing synthesis of natural products demands experience, talent and art. Longifolene is an illustrative example of a first disconnection noted from product to

Fig. 5 First disconnections by Corey. Arrows indicate the direction from product to reagent. Modified from Polanski, J., 2009. Chemoinformatics. In: Walczak, B., Tauler, R., Brown, S. (Eds.), *Comprehensive Chemometrics* vol. 4. Amsterdam: Elsevier, pp. 459–505.

reagent scheme (Fig. 5) (Corey and Cheng, 1989; Corey, 1993). Precisely the scheme designed by Corey in 1957 refers not to synthons but directly to reagents. The application of computers in the CASD method was also pioneered by Corey. As usually a single disconnection of TM does not solve the problem but the first level reactants must be disconnected further and further to the next level reagents, forming the so-called synthesis tree. Eventually, the availability of the reactants indicates a moment for the last level disconnection. Practically a full disconnection architecture appeared to be an extremely complex computational problem due to an expansion of a number of possible routes analyzed. For example, medium complexity synthesis can involve 10 level synthesis tree in which a number of precursors can exceed a thousand. The expansion of synthetic tree needs to be pruned (Barone and Chanon, 2003).

The strategy of CASD can be compared to the chess strategy where relatively simple laws result in a complex architecture of decision-making where human intuition and experience sometime can find optimal solutions at a first glance (Todd, 2005). Various successful paths are possible; however, the strategy and further paths are strongly limited by the early choices. The expansion of the decision-making tree usually needs pruning, usually by rules of thumb. Both games often rewards a gambit strategy. In chess we can open a game sacrificing a chess piece for the strategic advantages gained. In turn, an unexpected disconnection that breaks common chemical rules may appear a winning strategy. Basically, the CASD software is programmed to find synthons. An important part is also the generation of precursors and sketching synthetic route that corresponds to the decided disconnection tree. A first CASD software, Logic and Heuristics Applied to Synthetic Analysis (LHASA), was programmed in the late 1960' by Corey group (LHASA). Searching for disconnections was coded here by CHemistry TRaNslator (CHMTRN), chemical language constructed exceptionally for this purpose (Ott, 2004). In turn, *Chematica* is a recent retrosynthetic system based on the complete chemical information available (Szymkuc *et al.*, 2016). Accordingly, seven million chemicals connected by the number of reactions and catalogues 86,000 chemical rules. Cost-cutting measure is an important indication controlling synthesis paths, shorter and more economical paths are preferred, which nicely illustrates the scope of chemoinformatics (Fig. 1). A variety of other retrosynthetic software is currently available.

Computer Assisted Structure Elucidation

Chemical syntheses are designed to provide chemical compounds which structures usually are to be proved by analytical procedures and/or spectroscopic methods (MS, IR NMR) which use nowadays is a routine in modern chemistry. Chemistry as a soft science relatively early took advantage from the artificial intelligence methods which were adopted by chemometrics. This allowed us to develop an efficient Computer Assisted Structure Elucidation which engages both the domains of organic and analytical chemistry (Steinbeck, 2003).

Computer Assisted Knowledge Discovery

Currently, a database is an efficient replacement for a printed version of documentation that enables registration and identifications of chemical compounds. The database system can also be used for the extensive investigations and analyses of chemical data working in a teacher-like mode, modifying, falsifying, or improving existing models, or in other words extending our chemical knowledge. Such data extraction and analysis by database mining is nontrivial and can be an attractive tool giving us a novel and fresh insight into the architecture of chemistry in the approach that is referred to as the discovery of knowledge (Frawley *et al.*, 1991).

Typically, chemical databases equipped with molecular editor and the efficient user friendly searching machine allow us the advanced data queries of the complex syntax. The management of traditional printed information system cannot be any longer a competition for such a technology. Therefore, the last update of the printed BH version appeared in 1998. The printed handbook that has been developed as a breaking innovation in the 19th century science, has been finally overpowered by in silico technologies. Data mining enabled Computer Assisted Knowledge Discovery bringing a substantial improvement into chemical investigations. chemical data can be efficiently accessed and processed all together in a real time. A question appears if this has significantly influenced chemistry. The increased performance is the first issue. But can we really discover chemical laws on the basis of database mining? The answer is positive. To show several examples. The analysis of molecular weight MW of chemical compounds registered in the Beilstein database indicated for example the mean MW of the most commonly used substrates are those near 150 g/mol and the most common products near 250 g/mol. Interestingly this values did not changed between 1850 and 2004. In turn, the distribution of MW for druggable substances and this for all registered compounds are virtually identical (Fialkowski *et al.*, 2005). An *architecture of organic chemistry* was further outlined by Rucker and Meringer who described the difference between theoretical graphs and the graphs mapped by real chemical compounds registered in Beilstein (Rucker and Meringer, 2002). Technically, self-organizing neural network was used for knowledge discovery in the reaction databases (Chen and Gasteiger, 1997). For review in this area a reader can compare Ester and Sander (2000).

Biological data at unprecedented tera- and petabyte scales were generated recently and the integrated computational platforms (D'Souza *et al.*, 2017) or new visualization tools (Tsiolaki *et al.*, 2017) have been developed for the efficient data mining, accordingly.

Chemometrics – Adopting Mathematics to Chemistry and Chemistry to Mathematics

The origins of chemometrics are in analytical chemistry where the first applications of computers basically engaged the problems which were more of the mathematical than strictly chemical background. Clearly, this application is available on the relatively early stage of the development of computer science. The experience we got by chemometrics can be then applied to fully molecular problems which originated a domain of chemoinformatics. Chemometrics helped to increase the potential of informatics for in silico chemistry expanding at the same time the scope of interest of chemical computer simulations. Historically, chemometrics focuses on mathematics, including statistics, programming and so on (Wold, 1995). This explains why we use a term chemometrical analysis as a synonym of the application of the advanced statistical methods for the extraction of chemical knowledge from chemical data (Myshkin and Wang, 2003; Pierce *et al.*, 2005; Pytela *et al.*, 1994) or even in the more narrow sense as PCA or PLS analyses (Rodriguez-Barrios and Gago, 2004). Mathematics forms a common language generally understood by science. However, each science branch has its specific language. Accordingly, an efficient translator support can significantly enhance the quality and understanding of mathematics in chemistry. At the same time chemical problems can be formulated in a form suitable for mathematical applications.

Clearly, chemoinformatics is a broader term than chemometrics and sometime chemometrics is included here as a sub-discipline. Usually, however, chemometricians prefer to form an autonomous science.

Computer Assisted Molecular Design

With the increasing number of chemical compounds the kind of inflation of new compounds have appeared. Therefore, we need to indicate and design chemical compounds that would be interesting objects of investigations. The architecture of organic chemistry indicates chemical space interesting for chemists (Fialkowski *et al.*, 2005). Actually, a term molecular design focuses on two different rationale categories. First is a design of any compound or in other words synthesis design discussed in article Chemical Syntheses and Retro-Syntheses. Second design rationale relates more to property than structural design. Chemistry contributes to industry constructing a variety of chemicals of the crucial importance for a nowadays civilization such as drugs, preservatives, flavors, etc. However, individual chemical molecules having a certain property can be integrated with different chemical structures. Accordingly, we can arranged atoms in the molecules into a variety of combinations of the different compounds hopefully possessing individual properties as desired. In practice, the available molecular configurations even today depend upon synthetic capability of individual laboratories and current chemical technology. This mean molecular design is to some extent limited by synthetic capability. Are there any simple rules indicating a formation of useful chemical compounds? Surprisingly, some chemical frameworks are suggested to be preferred patterns in the drug molecules (Fattori, 2004; Kubinyi, 2006; Schneider and Schneider, 2017).

From Data to Drug Candidates and Drugs

Basically, a molecule of drug is a man-made moiety designed or discovered in other way to fit the biological counterpart and produce the required action. Accordingly, drugs are to manipulate biological effects generated by macromolecular proteins designated as targets or receptors (a precise definition of the receptor can be found in Cohen, 1996). Thus, the drug-receptor interactions define a potential activity. Currently we attempt to simulate these interactions in silico. Drug design or molecular design are two terms used as synonyms to refer to in silico technology in this area. This duality nicely illustrates the difference

between a molecule and a substance (drug). A term drug design scores high on optimism because currently we do not have an efficient technology to virtually construct a real drug in a single step engineering like process that would resemble for example the design of a bridge or a building. Therefore, precisely we can define molecular design as a method attempting to find *drug candidates* on the basis of computational techniques. Drug discovery or drug development are broader categories referring to the investigations (both in silico and in vitro) of drug candidates as potential drugs. Basically drugs can be developed by target based or phenotypic strategies (Swinney and Anthony, 2011). The analysis of the economic efficiency of current drug design R&D efficiency is pessimistic. The decreasing financial success is revealed and described in the so-called backward Moors (Erooms) law (Scannell *et al.*, 2012). Big pharma is driven by innovations. This means new drugs are needed for new patents capable of bringing new incomes. Therefore, companies are forced to fierce R&D search. At the same time regulations decided that development strategy was turned to target oriented approaches which, apparently, appeared too optimistic. Stiff quality and safety requirements and organizational factors could also be a success barrier here (Leeson and St-Gallay, 2011). On the other hand there are good examples of the successful drug design (Borman, 2005) and drugs get better and better imitating natural biological effectors.

Structure Based Design

What we mean by structure based design is a method that is based on the known receptor structure. Basically, two basic approaches of docking and de-novo design are available to fill of a receptor with a ligand structure (Schneider and Fechner, 2005). By docking we understand fitting the ligand structure into the receptor cavity (Kitchen *et al.*, 2004). Available programs are specified in Warren *et al.* (2006). In turn, in de-novo design a potential receptor ligand is constructed directly in the receptor cavity from the molecular fragments or even individual atoms. Available programs and illustrative examples are given in Warren *et al.* (2006), Kirkpatrick (2005). Docking protocols were used for High Throughput Screening (HTS) mode of in silico searching for the receptor ligands. The Intel-United Devices Cancer Research Project is here an example of internet distributed computing in which 3.5 billion molecules were investigated as potential anticancer drugs in the simulation performed by downloadable screensaver (Richards, 2002).

Recent advances in technology and novel approaches to drug discovery are now available in the context of the description of the target structure. This includes *structure, dynamics, mutational activation and inactivation, and signaling mechanisms*. An illustrative example can be small-molecule inhibitors of KRAS (Ostrem and Shokat, 2016). *Mechanism based design* is a term used as a formal term referring to such methods.

Ligand Based Design

Often not enough data for target receptor is available. In such a case the ligands that are known forms the basis for the comparison of the new molecular representations. This approach is known as a *ligand based design*. Accordingly, this method is based on the nondirect investigation of the ligand-target interactions or in other words *receptor or pharmacophore mapping* where a pharmacophore refers to the receptor or receptor sector model *reconstructed* from a series of its ligands. Depending upon individual method, pharmacophores or pseudoreceptors are usually assembled from virtual elements which can be represented by various functionalities, interaction types, or even fragments of molecules, e.g., aminoacids, atom or atom types. Actually, generally only very rarely any relation between a real receptor and a pharmacophore exists. Extensive review of the methods is available for example in Cohen (1996), Horvath *et al.* (2005).

Mapping Structure to Property in QSAR Approach

Quantitative structure activity relationship (QSAR) is a strategy of the essential importance for chemistry and pharmacy, based on the idea that when we change a structure of a molecule then also the activity or property of the substance will be modified. Structure modification can result from the virtual in silico operations, intentional in vitro projects (usually synthetic research) or we can just investigate available substances. The importance of the QSAR concept can be recognized by a volume of the literature and variants of the methods described. A brief introduction to this area can be found in Polanski (2009a,b), while current state of QSAR is thoroughly reviewed by Cherkasov *et al.* (2014). Basically, in QSAR we map chemical space to property space modeling a function relating property to chemical structure or more accurately to the molecular descriptors that are related to this chemical structure. This function should work like a dictionary between two spaces hopefully predicting the activity of novel compounds of the desired properties. Theoretically, these molecules can be then synthesized and tested as drug candidates while iterative QSAR modeling will further optimize second level synthetic targets and the property itself. Because a QSAR function relates property to structure, this is an indirect design of the molecular representations having this property (Polanski *et al.*, 2006).

Multidimensionality of QSAR (0-7D) relates to a complexity of the ligand or ligand-receptor data coded by molecular descriptors used during modeling. In the majority of examples QSARs are modeled without receptor data (receptor independent mode) but receptor dependent QSARs are also possible (Polanski, 2009a). In the majority of described applications QSAR realizes a strategy from molecules to property, however, an inverse strategy from property to molecules can also be hypothesized

(De Julian-Ortiz, 2000). According to the scope of chemoinformatics (Fig. 1) analyzing and/or modeling economic properties are hot issues that could significantly contribute to molecular design. Accordingly, the analysis of big data from molecular market was performed to obtain the first quantitative structure economy relationship (Polanski *et al.*, 2016).

Drug-Likeness and Druggability Concept

Data dependency and uncertainty is an immanent part of QSAR modeling (Polanski, 2009a; Polanski *et al.*, 2006) and we still do not have a technology that would be capable of designing in a single act a molecule having properties desired. Instead, molecular design is a method that improve the success ratio in a search for new drug candidates. Therefore, this kind of design prefers rather general than rigorous rules. The example can be the so-called drug-likeness concept insisting that some common features or even privileged substructures can be indicated in drugs. The Lipinski rule of five lists here molecular weight <500 , $\log P < 5$, a number of hydrogen bond acceptors <10 , and a number of hydrogen bond donors <5 that rule advantageous drug-likeness for the orally available drugs (Lipinski *et al.*, 1997). Precisely, the Lipinski rule focuses on molecular descriptors. In turn, the ADMET concept shifted our interest to the properties, in particular, these deciding compounds bioavailability and/or biocompatibility, i.e., Adsorption, Distribution, Metabolism, Elimination and Toxicology (Davis and Riley, 2004; Hodgson, 2001; Van de Waterbeemd, Gifford, 2003). Finally, a concept of privileged structures appeared. For example, it has been discovered that a “group of 32 common shapes or frameworks accounted for 50% of the 5120 molecules considered. Whether these fragments had intrinsic characteristics that gave them drug-like properties or their presence was a result of chemists’ habits, familiarities or synthetic versatility was an issue that was recognized but not addressed” (Fattori, 2004). NCI DTP AIDS Antiviral Screen database (40,000 compounds) was searched for the common frameworks and molecular fragment distribution typical for anti-HIV activity (Helma *et al.*, 2002). The related approach allowed Oprea to cluster more than 12,000 compounds into different activity levels (Oprea, 2004). Some privileged drug-like moieties can be found in Kubinyi (2006). Eventually, the comparative or combined QSAR databases appeared in a hope for identifying more molecular drug-likeness rules (Hansch *et al.*, 2002; Oprea, 2002). Shen *et al.* developed a concept of “the application of predictive QSAR as a virtual screening tool for database mining” (Shen *et al.*, 2004). Protein and gene expression data can be processed similarly to molecular representations (Helma *et al.*, 2002). Accordingly, druggability relates to the selected receptors that provide the privileged fit to drug-like molecules while we can look for druggable genomes expressing druggable proteoms (Lipinski and Hopkins, 2004).

Bioinformatics in Drug Design

In bioinformatics we focuses of the biological space rather than on the chemical one. Formally, we are mapping here the biological to chemical space. Pharmacogenomics is a concept that by the analysis of genomic data we can obtain novel drugs. Novel data measured form DNA microarray gene expression experiments pose new computational and processing challenges that formed bioinformatics to an important interdisciplinary research.

The relation of bioinformatics and chemoinformatics resembles this of chemoinformatics and chemometrics. Accordingly, chemoinformatics can be interpreted as a part of bioinformatics.

Internet Resources for Chemistry and Chemoinformatics

A first cable computer connection and networking took place in 1960’ in the United States. Nobody could have expected the expansion of social interaction by Internet. Nowadays, the impact of Internet on the economy and science is clear. Web technologies are more and more common in computer science and chemoinformatics. A number of chemical resources available in the web steadily increases. First of all, we can indicate a number of sites with chemical data. A variety of other web resources include educational materials, software (free or commercial), on-line chemistry journals and many others. E-commerce is also a common way of the distribution of chemicals. The enumeration of all available web sites that are of the interest for chemoinformatics is not possible any-longer in such a brief review. The addition to Wikipedia and Google and the enormous wide SMILES presence in web technologies are examples of the success of chemoinformatics.

Current Practices and Capabilities

Basically, the methods of chemoinformatics have been formed in 1990’ and early 2000’. Accordingly, a four volume Handbook of Chemoinformatics edited by Gasteiger (2003) is still the most comprehensive up-to-date introduction to the topic. Generally, what we observe recently is a move from method development to the efficient applications and vigorous software development. On one hand chemical informatics was moved into public domain. On the other hand still a lot of payable services are under development. In this context current practices follow general directions of computer related

technology development. A lot of the services are available. A mobile CAS service can be an illustrative example here. Chemoinformatics has answered the expectations and needs of pharma for new methods in computer-aided molecular design. Drug discovery and development is still the most important research field. Organization and utilization of drug discovery data involving small molecules, analysis of structure-activity relationships, and prediction of active compounds have remained hallmarks (Bajorath, 2015). Much higher computation capability, significantly higher and less expensive storage and memory provided significantly better opportunities for the information storage and processing. Docking is routinely used to identify potential hits from large compound libraries and Zanamivir and oseltamivir (Tamiflu) are examples of anti-influenza drugs developed in structure-based strategies which combined computer-based approaches, such as docking and pharmacophore-based virtual screening with X-ray crystallographic structural analyses (Mallipeddi *et al.*, 2014). Big data is a good example illustrating a level of the development of chemo and info counterparts of chemoinformatics. We need a proper structure of the data, in particular, the measured properties should be reliable, precise and extend enough to describe the complexity of the problem. For example, we usually analyze drug candidate action by the activity value versus a single target. In fact, however, a xenobiotic in an organism can induce a significant changes in signaling of various targets. This concept is known as polypharmacology. In this context, the polypharmacology and lipidomics inspired scheme of HTS data screening has been developed recently by Gabriele Cruciani group (Goracci *et al.*, 2017). The method is limited by an inexpensive and rapid procedure for the extraction and MS based determination of a medium size population of lipid species that can characterize the complex answer of any organism for a drug (drug candidate) administration. In 20 min this provides us a data on the serum concentration of 1000 different lipids in serum. Such a data can be arranged in a fingerprint-like lipid profile which if tested as a function of time, can give us a real information on the activity and toxicity of the xenobiotics used. This illustrated that more efficient big data methods are limited not necessarily by the statistical issues but by new technology in inexpensive property measurements (Polanski and Gasteiger, 2016). New HTS methods for property measurements should undoubtedly bring new quality in big data analyses in drug design. Another recent big data study is an attempt to model the Alzheimer disease. The extend experimental property measurement has been referred here as *smart data* approach (Geerts *et al.*, 2016). Femto or attosecond serial X-ray protein nanocrystallography which generates as much as 3 million. X-ray patterns (measured 3D structure data) in seconds (Chapman *et al.*, 2011) is another illustrative example.

Closing Remarks and Future Directions

We can interpret a formation of chemoinformatics as an answer to a fascination of the potential of in silico chemistry but also to the disappointment of computer assisted drug design in early 90'. A need to teach computers the essentials of chemistry not only provided us with new tools but also allowed us for better understanding of chemistry. Currently chemoinformatics is intelligent and flexible enough to adopt the uncertainty of fuzzy data produced by in vitro chemistry. In this context chemical ontology is an example of the trend which will probably be followed in silico. Molecular design and drug design are two terms used for the description of the main objective of chemoinformatics. This nicely illustrates the dichotomy between molecules and substances forming a class of chemical compounds. While molecules are represented mainly by molecular descriptors, properties represent substances. A flood of molecular descriptors is accompanied by property deficit. Properties are rare because their measurements are expensive. This means property predictions are often required. Property deficit explains low success ratio of drug design. In fact, the basic objective of chemoinformatics is a design of drug candidates by the search of advantageous molecular descriptors on the basis of few properties available. Then, we hope some of candidates will appear successful. Hopefully, with the physicalization of chemistry, properties will appear more available making drug candidates better. The example are *omics* methods which provided us with new technologies providing more and more property data. Big pharma is driven by innovation. To develop innovation capable of winning on the market these data should be cheap and capable for rapid measurements. Basically, we know how to efficiently transform the data into chemical knowledge and further into drug candidates. With the increasing availability of properties better quality of drug candidates will increase the success ratio in developing new drugs. New in silico methods are appearing and still are to appear with wider availability of the property data to efficiently treat this kind of data.

Nowdays Internet is a philosophy of the informatics, in particular, chemoinformatics. Chemistry depended on data and the web has conserved this dependency making the data broadly available. Our addiction to the Internet will definitely increase, stimulating also further cooperative development of the discipline.

Eventually, this text is a significantly shortened but at the same time revised and upgraded version of the article in the Elsevier Encyclopedia of Comprehensive Chemometrics.

Fingerprints and Pharmacophores

Daniela Schuster, Paracelsus Medical University of Salzburg, Salzburg, Austria

Introduction

In drug discovery and development as well as related fields such as toxicology or environmental chemical research, molecular similarity assessment is a central theme for various reasons. Comparing compounds and their properties may lead to information on the compound's physicochemical properties and even biological activities. Indeed, about 30% of compounds similar to an active compound have been reported to be active themselves (Martin *et al.*, 2002). Very often, researchers look out for similar compounds to identify related molecules, for example for studying structure-activity relationships. However, in many cases also dissimilar compounds are sought, for example when novel chemical scaffolds are acquired for a compound collection or when intellectual property opportunities are evaluated (Maggiora *et al.*, 2014).

Historically, similarity analysis was long based on fragment comparison or restricted to structurally very similar compound series. However, approaches describing the structures more completely and globally, thereby also allowing for more structural diversity within the studied data set, were needed (Cramer *et al.*, 1974). Nowadays, many similarity calculations and metrics are available (Cereto-Massagué *et al.*, 2015; Maggiora *et al.*, 2014); however, similarity assessment is still subjective and there is so far no consensus on the 'best' methodology.

This encyclopaedia entry will focus on two widely used similarity assessment methods: fingerprints and pharmacophore models. They represent global and local representations of the chemical structures involved in the comparison and therefore serve as examples to discuss this aspect as well.

Background and Fundamentals

Fingerprints are bit-string representations of molecular structure and properties. The bit-string encodes the absence (0) or presence (1) of a specific property, which can be a molecular structure or fragment. Depending on the method transforming the molecule into a bit-string, several types of fingerprints are available. While most of them are merely based on the 2D structure of the compounds, a few can also store 3D information. Fingerprints usually consider the whole molecule for generating the bit-string and are therefore classified as so-called global descriptors. They are straightforward to compute, and so fingerprint-based comparisons are among the fastest similarity calculations available.

Historically, the concept of a pharmacophore as the essential part of a drug determining its binding to a receptor was first presented by Paul Ehrlich (Ehrlich, 1898). The concept, its understanding and application evolved over the next decades (Güner and Bowen, 2014), and is nowadays an established and fundamental approach to understanding and predicting activities of small organic molecules. A pharmacophore model consists of the chemical and spatial arrangement of chemical functionalities, which are essential for the biological activity of a compound (Wermuth *et al.*, 1998). It contains so-called features like hydrogen bond acceptors/donors, hydrophobic areas, aromatic rings, positively or negatively ionizable groups or metal chelators. According to this definition, most features directly translate into target-ligand interactions essential for biological activity. Because only those crucial interaction points are considered when comparing compounds, pharmacophore models are classified as so-called local descriptors.

Approaches

The main fingerprint approaches include substructure keys-based fingerprints, topological fingerprints and circular fingerprints (Cereto-Massagué *et al.*, 2015). They differ in the way they are translating structural information into the final bit string. First, in the substructure keys-based fingerprints each bit stands for a chemical substructure, for example a carboxyl group, primary amine or phenyl. The individual fingerprints belonging into this group have a pre-set bit length and definitions at which position which substructure is encoded (Fig. 1).

Topological fingerprints analyze all the fragments of a molecule. Starting from each atom, a usually linear path up to a pre-defined number of bonds is followed. Each fragment produced in this procedure corresponds to a position in the bit string (Fig. 2).

The third class, the circular fingerprints, records the environment of each atom up to a determined radius (Fig. 3). These fingerprints are widely used for full structure similarity virtual screening.

Apart from directly describing a chemical structure, fingerprints can also represent other properties of molecules such as functional classes (functional class fingerprints, FCFP), pharmacophores (pharmacophore fingerprints, PF), reactions (reaction fingerprints, RF) and others.

Once the bit-strings resulting from the individual approaches are calculated, the similarities of the compared molecules need to be quantified. In principle, several similarity coefficients are available to choose from, for example the Tanimoto, Cosine,

Fig. 1 Substructure keys-based fingerprints translate the presence or absence of chemical substructures into a bit string.

Fig. 2 The concept of topological fingerprints exemplified on the primary amino group of the molecule. Depending on the pre-set number of bonds, several linear pathway fragments are produced, which are then translated into a bit string.

Hamming, Russell-Rao or Forbes coefficients (Willett, 2006). In the last decade, the Tanimoto coefficient (TC) has evolved as the dominating similarity function. It is calculated according to Eq. (1)

$$TC = \frac{c}{a + b - c} \quad (1)$$

where the two compared molecules have a and b bit-sets in their fragment bit-strings and c of these bits are found in both of the bit-strings. The TC has values between 0 and 1, sometimes also expressed in percent. A value of 0 means no similarity, while 1 is calculated for identical molecules. A TC of ≥ 0.85 is considered to describe two quite similar compounds (Martin *et al.*, 2002).

Also pharmacophore models can be seen as a kind of fingerprint for a molecule. Each substructure of a molecule can be translated into a pharmacophore feature, such as for example a hydrogen bond acceptor, and a fingerprint can be created featuring the presence or absence of these features. However and more often, 3D pharmacophore models are created and used to identify chemical functionalities essential for biological activity and to search large 3D molecular databases for fitting, putatively active compounds.

In the ligand-based approach, active molecules are first transformed into 3D conformational models. These consist of representative sets of energetically favorable 3D structures for known active molecules. Those 3D structures are then superimposed in a way that equal chemical functionalities overlay. Most algorithms start with the most rigid active molecules, for which this 3D alignment is rather straightforward, and then proceed with more and more flexible molecules, which are aligned onto the more rigid ones. Finally, pharmacophore features are placed in the 3D space where chemical functionalities are common between the active molecules, which is called the common features or active analogue approach (Fig. 4).

There is usually a need for spatial restriction of the ligands to prevent large molecules from being reported as hits, which are likely too spacious to fit into the binding site. Technically, so-called exclusion volumes – forbidden areas for the ligands – are placed in the space surrounding the locations where the active molecules fit. If available, inactive molecules fitting the features of the pharmacophore can be used to strategically place exclusion volumes outside the active molecules' volumes.

Fig. 3 Circular fingerprints start at a central atom and then consider the molecular environment in a pre-set diameter of e.g., two or four bonds, respectively. The thereby generated fragments are then translated into a bit string.

Fig. 4 Ligand-based pharmacophore model generation exemplified on three histamine A_2 receptor antagonists. Starting from a 2D structure, corresponding 3D structures and conformational models are calculated for the training ligands. The conformers are then aligned in a way that equal chemical functionalities overlay. Finally, pharmacophore features are placed on these common functionality locations. In this example, the aromatic ring feature is shown in blue, hydrogen bond donor points as green, and hydrogen bond acceptor points in red.

If there is a high quality data set available, the development of quantitative pharmacophore models aimed to predict a compound's potency is also feasible. The main limitation in this respect is the data quality. For model generation, at least 16 molecules spanning four orders of magnitude of activity, all tested in the same assay, and preferably in the same lab are required. Ideally, many more ligands from the same test are available for quantitative model validation afterwards. This stringent requirements often hamper the generation of quantitative pharmacophore models that are especially useful for ligand optimization.

In the structure-based pharmacophore modeling approach, the 3D structure of the target is known – ideally complexed to a bioactive molecule. This 3D structure can be derived experimentally by X-ray crystallography or NMR studies. Alternatively,

Fig. 5 The workflow of structure-based pharmacophore model generation exemplified on the δ opioid receptor antagonist naltrindole co-crystallized with its target (Protein Data Bank entry 4ej4). Starting from the 3D complex, the focus is put on just the direct environment of the ligand binding site. The ligand's surrounding amino acids are analyzed for possible direct interactions with the ligand based on their chemical functionalities, distances and contact angles. At interacting positions, pharmacophore features (yellow – hydrophobic, blue star – positively ionizable, red arrow – hydrogen bond acceptor) are placed. Exclusion volumes (grey) are placed on amino acid side chains forming the binding site. Finally, all information on the receptor and the ligand are deleted and the interaction pattern with the exclusion volumes remains as an abstract representation of binding requirements. This is the starting point for model validation, optimization and use in virtual screening.

theoretical target models, so-called homology models, with a docked active molecule can serve as basis for the model. In a first step, all observed target-ligand interactions are mapped onto the respective parts of the ligand (Fig. 5).

Such interaction models usually consist of far more chemical features than are necessary for biological activity. So how can the modeler find out which are the more important features? If the data situation is good, information can come from mutational analysis and other 3D target-ligand complexes. Amino acid mutants leading to a change of ligand affinity can help to identify important anchoring points for the molecule. Additionally, interactions observed in several target-ligand complexes most likely play an important role for activity modulation (Sun *et al.*, 2011). Furthermore, interaction maps from molecular dynamics simulations can help to prioritize specific interactions (Moorthy *et al.*, 2016). If such data is not available, a so-called test data set containing active and inactive compounds can help. The initial interaction model is systematically altered and applied to screen the test set. Any alteration that leads to a better retrieval of active compounds and no increase of found inactive compounds is a step towards a more general and representative model for modulators of the respective target. Furthermore, exclusion volumes can be strategically placed on amino acid residues lining the binding site (Vuorinen *et al.*, 2014). This strategy can also be followed to optimize ligand-based models.

Shape-based searches and pharmacophore features are frequently combined. Many pharmacophore modeling tools include a shape 'feature', which is derived from the shape and volume of active compounds fitting the model. The shape is included as a spatial restriction of the size of fitting hits. Also some shape-based screening programs like Openeyes ROCS can include pharmacophore-like features, which are termed color features. Although they may not be directly comparable with true physico-chemical property-based pharmacophore features, they share several functionalities such as 'hydrogen bond acceptor', 'hydrogen bond donor', 'negative charge', and some more. Another shape-pharmacophore-combining screening algorithm is the ultrafast shape recognition with CREDO atom types (USRCAT, Schreyer and Blundell, 2012).

Protein binding site-based pharmacophore models can be used for model generation without prior knowledge of active ligands. A so-called grid is calculated on the binding site surface and analyzed for potential interaction points for ligand binding (Fig. 6). According to available interacting amino acid residues, locations for pharmacophore features are suggested, where the modeler can place the respective features.

Similarly, pharmacophore-based docking has been reported. One of these approaches is PharmDock (Hu and Lill, 2014). It can be used for pose prediction and compound ranking like docking programs, thereby being much faster than common docking algorithms. The pharmacophore-guided docking has been shown to be superior over unbiased docking, which is not surprising. Unbiased docking lacks information on the really important interactions in the binding site, while pharmacophore-guided docking includes this information, which is added in the workflow development. However, docking with constraints forcing a docking ligand to establish certain interactions may eventually lead to similar results as the pharmacophore-guided approach. Like

Fig. 6 Visualized grid for positively ionizable ligand functionalities (blue) surrounding Asp128 in the δ opioid receptor binding site (4ej4). The empty binding site is filled with small dots representing possible locations for respective pharmacophore features. The individual dots can be selected for placing the features and manually constructing a model filling the binding site with complementary functionalities.

all other docking approaches, the inaccuracies of the available scoring functions in predicting binding affinities limit the use of pharmacophore-guided docking in compound optimization.

Illustrative Examples and Case Studies

Fingerprint-based similarity searches are widely used in cheminformatics. Large bioactivity databases like ChEMBL (Bento *et al.*, 2014) and PubChem (Wang *et al.*, 2017a) as well as chemical databases such as the SciFinder database operated by Chemical Abstracts Service have implemented fingerprints to search for similar molecules with defined Tanimoto coefficient range. A broad similarity search in various, huge databases using different fingerprints is implemented in the SwissSimilarity platform (Zoete *et al.*, 2016). For database analysis and library design, fingerprint methods are used to group similar compounds and evaluate databases for their structural diversity. They are also used to represent whole compound libraries for comparison amongst each other (Fernández de Gortari *et al.*, 2017). Furthermore they are successfully used for comparing chemical structures with compounds of known bioactivities or ensembles thereof, for example the ECFP4-based similarity ensemble approach (SEA) prediction platform (Keiser *et al.*, 2007). This tool has been successfully used for identifying off-target effects for a variety of approved drugs (Keiser *et al.*, 2009). For example amitriptyline has been identified as a nanomolar serotonin transporter inhibitor in this study, which has been previously unknown. The SEA platform has also been used to find a target for the natural product miconidin acetate (Zatelli *et al.*, 2016). In studies comparing several virtual screening approaches for their predictive power, SEA proved to be very successful in finding new active compounds (Kaserer *et al.*, 2015, 2016). However, the correct classification of inactive compounds turned out to be a challenge, possibly because the structure-activity database in the background is a limited source of information on inactive compounds. Another example for a fingerprint-based profiler is the SwissTargetPrediction platform, which uses 2D fingerprints besides 3D similarity measures for assessing ligand similarities and associations to putative targets (Gfeller *et al.*, 2014). Other fingerprint-based activity prediction tools include SuperPred (Nickel *et al.*, 2014), MOST (Huang *et al.*, 2017) and the polypharmacology browser, which even combines 10 fingerprints for similarity assessment (Awale and Reymond, 2017).

Pharmacophore models are established as useful tools to discover novel active compounds for specific targets, predict mechanism-based side effects or calculate a bioactivity profile for a molecule. For example, Markt *et al.* (2009) used two ligand-based, shape-restricted pharmacophore models for the discovery of novel cannabinoid receptor 2 (CB₂) ligands. From a training set of five potent CB₂ ligands, common feature pharmacophore models were generated and merged with one of the training compound's shape, respectively. A test set of 15 active CB₂ ligands and over 67,000 decoys (putative inactive compounds) were used to determine the enrichment of active compounds in a virtual screening setting. The two best performing models were selected and employed to virtually screen commercial compound databases. From initially over 920,000 compounds in the databases, nearly 30,000 fitted into either or both models. Further filtering using physicochemical properties, structural similarity analysis and visual inspection led to the selection of 14 hits for biological evaluation. Out of these 14 compounds, three showed K_i values ≤ 2 μ M, which corresponds to a success rate of over 20% true positive hits.

A classical side effect modeling study was performed by Kratz *et al.* (2014). They assembled a data set of human ether-a-go-go-related (hERG) potassium channel blockers. In the course of this study, not just one but a whole set of models was created for hERG blockers. This is because one pharmacophore model is unable to predict all active molecules for a target. Usually, this

Fig. 7 The parallel use of several complementary pharmacophore models allows for a more complete retrieval of active compounds. The cloud incorporates a database of active (rose) and inactive (white) compounds. Each model used for screening derives a hit list of fitting compounds (green circles). While a single model only finds a fraction of true active compounds, the parallel use of models finding mostly different active compounds improves the overall retrieval of active molecules.

doesn't pose a problem because in a "cherry picking" scenario, the scientists are interested to find some hits for further development. In side effect studies however, the project aims to identify all potentially harmful compounds. Therefore, several models have to be generated for an adverse effect target not to miss the majority of active hits (Fig. 7).

The model set by Kratz *et al.* was applied to databases containing synthetic and natural products and successfully identified 13 previously unknown hERG blockers from 50 experimentally tested virtual hits.

Sometimes also the use of several pharmacophore modeling tools is beneficial because they may find complementary active hits. Temml *et al.* (2014) generated structure-based pharmacophore models from one cyclooxygenase-2 – inhibitor X-ray crystal structure using the two pharmacophore modeling programs LigandScout and Catalyst (implemented in Discovery Studio). The LigandScout model found 53 virtual hits and the Discovery Studio model 74 hits, respectively. Surprisingly, not a single hit was present in both hit lists. However, when 10 virtual hits from every hit list were biologically tested, each found 4 active compounds, respectively. So although the resulting hits of the virtual screening were completely different, each of the programs retrieved active hits.

The concept of using several models can be further expanded by applying several models for a broad set of targets. This concept is termed pharmacophore-based parallel screening or pharmacophore-based target fishing. The openly available online platform PharmMapper offers over 53,000 structure-based pharmacophore models for activity predictions (Wang *et al.*, 2017b). In comparative studies on virtual screening tools, PharmMapper performed well for cherry picking with 11 active compounds out of 19 hits predicted for cyclooxygenase (Kaserer *et al.*, 2015) and one active ligand out of two predicted ones for the peroxisome proliferator-activated receptor γ (Kaserer *et al.*, 2016), respectively. However, many active molecules from these studies were not found by this platform. Additionally, several companies offer pharmacophore databases along with their software such as Biovia Discovery Studio (PharmaDB; see Relevant Websites section) and inte:ligand (pharmacophoreDB; see Relevant Websites section). Examples from the academia include target fishing for compounds of the herbal remedy *Ruta graveolens* (Rollinger *et al.*, 2010) and the natural product leoligin, the main lignan from *Leontopodium alpinum* (Duwensee *et al.*, 2011).

Results and Discussion

Fingerprint-based methods and pharmacophore models are established and important tools in cheminformatics and virtual screening. They are likewise used in industry and in the academic field. A wide variety of fingerprints are available and used for comparing molecules for diverse purposes. In library analysis, they are important to identify the chemical diversity of a compound collection, which is regarded as beneficial for drug discovery libraries. Also when planning to purchase new compounds, fingerprint methods can report if the compounds to purchase have sufficient dissimilarity to the substances that are already on stock.

Because of their speed, fingerprint-based methods are very popular for activity predictions, especially in the field of target fishing, where query compounds are compared against millions of compounds with known activities. More and more platforms based on fingerprints are published each year and most of them are publicly available. However, success stories reporting a prospective use of these tools are rare and therefore their predictive power still needs to be critically evaluated and compared to other tools. At some point one gets the impression that developing new tools may not be meaningful unless the existing platforms have been properly validated and their strengths and weaknesses have been revealed. First validation studies suggest that the predictive power in the identification of active compounds is satisfying but still highly depending on the activity database in the background. For the same reason, the correct prediction of inactive compounds seems to remain a challenge, but will improve with the growing amount of structure-activity data. A combination with other tools that are more powerful in this respect may be a good strategy to overcome this current drawback.

In comparison, success studies reporting prospective pharmacophore-based applications are easy to spot in the scientific literature as exemplified above. Pharmacophore models are used as standalone virtual screening tools or used in combination with physicochemical filtering, structural clustering, shape-based screening or docking or a combination thereof. Nowadays, pharmacophore modeling software

like many other virtual screening tools is convenient to use, with an easy to navigate graphical user interface and sometimes even ‘wizards’ that guide through the model generation process. This easy-to-use mentality sometimes distracts from the actually very sophisticated process of model development. At the beginning, a data set for model generation and theoretical validation is to be assembled. This data need to be of high quality and be derived from suitable assays. Essentially, if a model should reflect binding to a specific protein target, also data reporting the direct binding to this target needs to be used for the modeling. Data from cell-based assays, where also other events than direct ligand binding influence activity, are not suitable. Model generation is technically not a challenge any more, which makes a rigorous validation protocol crucial. Theoretical model optimization and validation using independent data sets must be followed by a prospective, experimental evaluation of virtual hits. The validation experiments must also comply with the rules for the data set. For instance, watching cells die is not a proof for kinase inhibition or any other specific mechanism of action. Cell-free, target-based binding assays are required to prove the pharmacophore hypothesis. Models lacking high quality experimental validation are of very limited value and journals should carefully consider if they are worth publishing at all. Of course, favorable hits should also be active in cell-based systems, but this is only the second step after prospective model validation.

Excitingly, many *in silico* tools are nowadays openly available to the public, either as online platforms operated on a remote server or as stand-alone programs that can be downloaded and locally installed on the workstation (Pirhadi *et al.*, 2016). This way, those tools are freely accessible to interested scientists all over the world for a more targeted planning of experimental work.

Future Directions

Both fingerprint-based methods and pharmacophore modeling have been successfully employed in a variety of research projects and are important, established tools in the analysis and discovery of active compounds. However, there is also room for improvement for both approaches.

Regarding fingerprint-based target fishing, the community currently seems to be struggling with quantitative target ranking. How shall hundreds of predicted targets be judged by the user? Which ones are the most probable ones and should be prioritized for experimental evaluation? There is currently a need to introduce a measure of significance for these tools, which enable an estimation of the chance that a virtually predicted activity is indeed probable. While there are first attempts in the field (Vogt and Bajorath, 2017), it will be a long way to go until these more sophisticated measures are implemented into the similarity-based target fishing tools. Furthermore, new fingerprint algorithms are reported regularly and their optimal application in similarity screening need to be determined.

The pharmacophore modeling branch currently suffers from severe drawbacks in feature definition and screening algorithms that rely on different concepts (Temml *et al.*, 2014; Wolber *et al.*, 2008). This leads to incompatibilities between different software or – even worse – sometimes between different versions of the same software. It will be a challenge to bring feature definitions to an up-to-date state including halogen bonds and sulfur bonds as well as a better consideration of internal hydrogen bonds in model fitting. Furthermore, hydrophobic areas are currently represented as globular spheres in the programs, which doesn’t reflect reality. Adjusting the hydrophobic contacts feature to more accurate geometries may also improve quantitative scoring of hit molecules. Finally, incorporating protein-ligand-contact information from molecular dynamics simulations in the development of pharmacophore models will lead to a better understanding of ligand binding and more predictive models in the future.

Closing Remarks

Fingerprints and pharmacophore models are indispensable methods in drug research. As in every cheminformatics field, research in the fingerprint and pharmacophore area is very active and there is constant progress in the improvement of the available tools and development of new approaches. Nevertheless, critical validation studies and especially benchmarking and prospective case studies are essential to identify the power and also the pitfalls of new developments. It is also important to see and apply these tools in context with other property calculation and virtual screening tools to make the most out of them.

Introduction

For the past decade, the amount of chemical data available in the public domain has been rapidly increasing (Cheng *et al.*, 2014; Hu and Bajorath, 2012; Nicola *et al.*, 2012). This led to the establishment of many databases that collect, curate, and disseminate publicly available chemical information with the aim of providing easier access to and better utility of these data (Akhondi *et al.*, 2012; Hersey *et al.*, 2015; Lipinski *et al.*, 2015; Ma *et al.*, 2012; Muresan *et al.*, 2011; Nicola *et al.*, 2012; Tiikkainen and Franke, 2012; Tiikkainen *et al.*, 2013; Williams, 2008a,b; Williams *et al.*, 2012). Importantly, these databases annotate chemical data with information from other scientific domains (such as genetics, genomics, pharmacology, toxicology, medicine, bioinformatics, and systems biology), assisting biomedical researchers in taking advantage of these public data for the discovery of new medications. To maximize the usefulness of the public chemical data, scientists should be aware of which databases have the information they need, and know how to exploit their full potential.

This paper provides a brief overview of some important chemical databases available in the public domain (see Fig. 1). Their uniform resource locators (URLs) are listed in Fig. 1 as well as in the Relevant Websites section at the end of this article. These databases vary in data contents, size, and quality (see Figs. 1 and 2) (Akhondi *et al.*, 2012; Hersey *et al.*, 2015; Lipinski *et al.*, 2015; Muresan *et al.*, 2011; Tiikkainen and Franke, 2012; Tiikkainen *et al.*, 2013; Williams *et al.*, 2012). Some of them provide a wide variety of information on millions of molecules, aggregated from hundreds of data sources. Others contain specialized information for a few thousand molecules, manually curated from peer-reviewed scientific articles. Because data exchange between these public databases is a very common practice, there are some overlaps in the data contents, but each database does have unique contents valuable to the scientific community. While they provide various tools and services for searching, browsing, visualization, download, programmatic access, etc., the primary focus of this article is on their data contents, to provide some guidance on what database to use to get a particular kind of information.

• PubChem (https://pubchem.ncbi.nlm.nih.gov) Provides comprehensive information on >93 million unique compounds, collected from >500 data sources, along with experimentally determined bioactivity data.
• ChemSpider (http://www.chemspider.com) Contains information for >59 million compounds, collected from ~500 data sources.
• ChEMBL (https://www.ebi.ac.uk/chembl/) Contains information on bioactive drug-like small molecules and their bioactivities, abstracted from literature.
• BindingDB (https://www.bindingdb.org) Contains experimental binding affinities, focusing on the interactions of proteins considered to be drug-targets with drug-like small molecules.
• PDBbind (http://www.pdbbind.org.cn) Provides experimental binding affinity data for the biomolecular complexes archived in PDB.
• Binding MOAD (http://www.bindingmoad.org) Provides experimental binding affinity data for the high-quality structures of protein-ligand complexes derived from PDB.
• DrugBank (https://www.drugbank.ca) Provides comprehensive information for FDA-approved and investigational drugs.
• IUPHAR/BPS Guide To PHARMACOLOGY (http://www.guidetopharmacology.org) Contains structures of small molecule ligands, peptides, and antibodies, with their affinities at protein targets.
• PharmGKB (Pharmacogenomics Knowledge Base) (https://www.pharmgkb.org) Provides curated information about the impact of genetic variation on drug response.
• SIDER (Side Effect Resource) (http://sideeffects.embl.de) Provides information on adverse drug reactions (ADRs) for drugs, extracted from drug labels and package inserts.
• Comparative Toxicogenomics Database (CTD) (https://ctdbase.org) Provides information on interactions between chemicals and genes/proteins and their relationship to diseases.
• Hazardous Substances Data Bank (HSDB) (https://www.toxnet.nlm.nih.gov/newtoxnet/hsdb.htm) Provides toxicological information for more than 5,800 potentially hazardous chemicals.
• Chemical Entities of Biological Interest (ChEBI) (https://www.ebi.ac.uk/chebi/) A freely available dictionary of molecular entities, focused on small chemical compounds.
• Human Metabolome Database (HMDB) (http://www.hmdb.ca) Contains detailed information about small molecule metabolites found in the human body.
• UniChem (https://www.ebi.ac.uk/unichem/) A free compound identifier mapping service, containing more than 145 million chemical structures stored in >30 databases.

Fig. 1 List of public chemical databases discussed in this paper.

Large-Scale Data Aggregators

PubChem

PubChem (Kim, 2016; Kim *et al.*, 2016a; Wang *et al.*, 2017) is a public chemical information resource, developed and maintained by the National Center for Biotechnology Information (NCBI) at the National Library of Medicine (NLM), an institute within the U.S. National Institutes of Health (NIH). It collects chemical substance descriptions and their biological activities from more than 500 data sources and disseminates these data to the public free of charge. Since the launch in 2004 as a component of the NIH Molecular Libraries Roadmap Initiatives, PubChem has been a key information resource for biomedical research communities in many areas such as cheminformatics, chemical biology, medicinal chemistry, and drug discovery.

PubChem contains various types of chemical information, including 2-D and 3-D structures, chemical and physical properties, bioactivity data, pharmacology, toxicology, drug target, metabolism, safety and handling, relevant patents and scientific papers, etc. While the majority of PubChem's records are about small molecules, it also contains information on a broad range of chemical

Fig. 2 Number of chemical structures contained in the databases discussed in the present paper (as of June 2017).

Fig. 3 Data organization in PubChem. PubChem organizes its data into three inter-linked databases called Substance, Compound, and BioAssay. SID, CID, and AID are record identifiers used in the Substance, Compound, and BioAssay databases, respectively.

entities, including siRNAs, miRNAs, carbohydrates, lipids, peptides, chemically modified macromolecules, and many others. These data are provided by various contributors, including government agencies, university labs, pharmaceutical companies, chemical vendors, publishers and a number of chemical biology resources. Most of the chemical databases discussed in this paper also contribute their data to PubChem.

As shown in **Fig. 3**, PubChem organizes its data into three inter-linked databases: Substance, Compound, and BioAssay (Kim *et al.*, 2016a) (see the Relevant Websites section). The Substance database contains chemical substance descriptions submitted by individual data depositors. Unique chemical structures are extracted from the Substance database and stored in the Compound database. The BioAssay database contains descriptions and results of biological assay experiments performed on chemical

PubChem	- Served as a central data repository for the NIH's Molecular Libraries Program (MLP) - Mostly high-throughput screening (HTS) data from NIH's MLP and other HTS projects. - Also contains literature-extracted screening data submitted by data contributors.
ChEMBL	- Bioactivity data for binding, functional, and ADMET assays. - Extracted from scientific articles in medicinal chemistry and natural product domains. - Also contains bioactivity data from deposited data sets.
BindingDB	- Quantitative binding affinity data extracted from scientific articles and patent documents. - Also captures key experimental conditions such as temperature, pH, and buffer composition. - Focuses on complexes between potential drug targets and drug-like small molecules.
PDBbind	- Quantitative binding affinity data extracted from scientific articles. - Covers protein-ligand complexes stored in PDB (with any resolution). - Also compiles the refined and core sets to provide high-quality data.
Binding MOAD	- Quantitative binding affinity data extracted from scientific articles. - Focuses on protein-ligand complexes stored in PDB with a resolution of 2.5 Å or better. - Provides a non-redundant data set that removes biases due to overrepresented proteins in PDB.

Fig. 4 Comparison of PubChem and other databases that provide bioactivity data of small molecules.

substances. The records in the Substance, Compound, and BioAssay databases are called substances, compounds, and bioassays, respectively. Similarly, the record accessions used for the respective PubChem databases are the Substance ID (SID), Compound ID (CID), and Assay ID (AID). Currently, PubChem contains more than 234 million depositor-provided substances, 93 million unique compounds, and 233 million bioactivity test results from 1.25 million bioassays, covering more than 10,000 protein target sequences.

Although this article describes PubChem under Section Large-Scale Data Aggregators, it should be emphasized that PubChem contains the largest amount of bioactivity data available in the public domain. These data are primarily generated from high-throughput screening (HTS) experiments, because PubChem served as a central repository for the now-concluded NIH's Molecular Libraries Program (MLP). However, it also contains a substantial amount of high-quality bioactivity data extracted from research articles and patent documents, thanks to data contributions by many bioactivity databases, including ChEMBL, BindingDB, and PDBbind (to be discussed later in the present paper) (Kim *et al.*, 2016b). In Fig. 4, the PubChem BioAssay database is compared with other bioactivity databases discussed in the present article.

ChemSpider

Another example of large-scale chemical data aggregators in the public domain is ChemSpider, owned by the Royal Society of Chemistry (RSC) (Williams and Tkachenko, 2014; Pence and Williams, 2010). ChemSpider provides information for ~59 million unique chemical structures integrated from ~500 data sources. To improve the accuracy of the data, it uses a crowdsourcing approach, in which registered users can enter information as well as annotate and curate the records. Especially, users can upload various spectral data for chemicals, including infrared, Raman, nuclear magnetic resonance (NMR), and mass spectra, and ChemSpider displays these spectra in an interactive visualization widget that allows zooming and expansion.

ChemSpider extends the crowdsourcing capabilities to chemical reactions and syntheses, by providing a database service called ChemSpider SyntheticPages (CSSP; see the Relevant Websites section). CSSP is essentially a publishing platform through which a short article about a chemical synthesis procedure is submitted by the user and published after rapid review by one or two editorial board members (typically within 48 h). Once published, it can be commented on by the community. All published articles are assigned digital object identifiers (DOI), making them searchable and citable.

Bioactivity Databases

ChEMBL

ChEMBL is a large-scale bioactivity database developed by the European Bioinformatics Institute (EBI), a part of the European Molecular Biology Laboratory (EMBL) (Gaulton *et al.*, 2012, 2017; Bento *et al.*, 2014). The majority of the bioactivity data in

ChEMBL are manually extracted from the full text of peer-reviewed scientific articles published in a variety of journals in medicinal chemistry and natural product domain. From each publication, the details of the compounds tested, the assays performed and any target information for these assays are extracted. These data are further curated and standardized to maximize their quality and utility across a wide range of chemical biology and drug-discovery research problems.

ChEMBL regularly updates its data, with new releases every 3–4 months. The current release of ChEMBL (release 23) provides information extracted from >67,000 publications and ~50 deposited data sets. In total, it contains >14 million bioactivity values for >1.7 million unique compounds from >1.3 million assays. These assays cover more than 11,000 targets (including ~4300 human protein targets).

While ChEMBL's primary focus is on the bioactivity data extracted from the medicinal chemistry literature, it also collects bioactivity data and annotations from various sources. For example, ChEMBL contains a subset of PubChem's bioactivity data (for confirmatory assays with dose-response endpoints). In addition, bioactivity data extracted by BindingDB from patent documents are integrated into ChEMBL (see Section BindingDB below). Recently, ChEMBL's data scope has expanded to several new areas, including data sets from neglected disease screening, crop protection data for agrochemicals, and drug metabolism and disposition data (Gaulton *et al.*, 2017).

It is worth mentioning more about data exchange between ChEMBL and PubChem (Kim, 2016; Gaulton *et al.*, 2012; Kim *et al.*, 2016a). ChEMBL focuses on compiling bioactivity data for drug-like small molecules that can perturb a biological system in a dose-response way. With that said, the majority of PubChem's bioassay data are not suitable for ChEMBL's data collection, because they were generated from HTS experiments that measured bioactivity of a large number of molecules typically at a "single" concentration. However, a small portion of PubChem assays (confirmatory and panel assays with dose-response endpoints) are within the scope of ChEMBL's data coverage, and have been loaded into ChEMBL. In turn, all ChEMBL assays derived from literature are integrated into PubChem.

BindingDB

BindingDB is a database of experimental protein-ligand affinity data, focusing primarily on proteins considered to be drug targets and their interactions with drug-like small molecules (Gilson *et al.*, 2016; Liu *et al.*, 2007). It currently contains more than 1.3 million binding data between ~7000 protein targets and ~600,000 small molecules. Many of these data are manually curated from scientific journals in the chemical biology and biochemistry domains. BindingDB captures not only the quantitative affinity data (e.g., IC_{50} , K_i , and K_d) but also important experimental conditions such as the temperature, pH, and buffer composition. In addition, it extracts quantitative binding data from patent documents. This patent-derived bioactivity data set is a valuable resource, considering that most of them are not reported in journal articles and that curation efforts in other databases (e.g., SureChEMBL; Papadatos *et al.*, 2016) usually focuses on chemical "mentions" in patent documents without capturing quantitative binding affinity values.

BindingDB also contains affinity data collected from other public databases, such as PubChem (Wang *et al.*, 2017) and ChEMBL (Gaulton *et al.*, 2017), while BindingDB's data are integrated into them in turn. Because BindingDB aims to collect binding affinity data for protein-ligand complexes, it imports ChEMBL's binding assay data but excludes those from functional and ADMET assays. Similarly, PubChem's confirmatory assays with binding affinity data are integrated into BindingDB, whereas PubChem's primary screening data are not imported in BindingDB because they are mostly HTS data generated at a single concentration.

PDBbind

The PDBbind database (Liu *et al.*, 2015) provides experimentally measured binding data for the biomolecular complexes archived in the Protein Data Bank (PDB) (Berman *et al.*, 2003). While PDBbind was originally created at the University of Michigan in 2004 (Wang *et al.*, 2004), it has been maintained and further developed since 2007 at the Shanghai Institute of Organic Chemistry. The biomolecular complexes covered by PDBbind include: (1) complexes between proteins and small molecule ligands; (2) complexes between nucleic acids and small molecule ligands; (3) complexes between two proteins; and (4) complexes between protein and nucleic acid.

High-quality data sets are required for developing and validating molecular docking and scoring functions for structure-based drug design. However, the data quality in PDBbind varies in terms of the resolution of the protein-ligand structures as well as the accuracy of binding affinities. To address this issue, PDBbind provides the "refined set," which consists of high-quality protein-ligand complexes selected by applying a set of rules that ensure the quality of the complex structures and binding data as well as the biological/chemical nature of the complex (Li *et al.*, 2014).

Whereas the refined set contains high-quality data, it is not appropriate to use as a standard benchmark set for evaluating docking/scoring methods, because it suffers from a substantial sample redundancy. For example, ~10% of the complexes in the refined set are those with HIV-1 protease (Liu *et al.*, 2015). Therefore, the refined set was further reduced to the "core set" through a systematic, non-redundant sampling after grouping proteins into clusters with a 90% sequence identity cut off (Li *et al.*, 2014). Relative to these refined and core sets, the entire PDBbind data set is called the "general" set.

PDBbind updates its data annually to keep up with the growth of PDB, along with updated refined and core sets. Currently, PDBbind (v.2016) contains the binding data of 16,179 biomolecular complexes, including 13,308 protein-ligand, 118 nucleic

acid-ligand, 777 protein-nucleic acid, and 1976 protein-protein complexes. The refined set of this release contains 4057 protein-ligand complexes, which are further reduced to the core set of 290 complexes in 58 protein clusters.

Binding MOAD

Binding MOAD provides high-quality structures of protein-ligand complexes derived from PDB (with a resolution of 2.5 Å or better) and, where available, their experimental binding affinity data (K_d , K_i , and IC_{50}) (Ahmed *et al.*, 2015; Benson *et al.*, 2008; Hu *et al.*, 2005). The data in Binding MOAD are validated through manual curations of the references cited within the PDB structure file. The proteins are clustered into different families based on 90% sequence identity, and one representative protein is selected from each family (typically, the one complexed with the tightest-binding ligand). This allows BindingDB to provide a non-redundant data set that removes biases from proteins heavily represented in the PDB. The current version of Binding MOAD (released in 2014) contains 25,769 complexes between 12,440 distinct ligands and 7599 distinct protein families, along with 9142 binding affinities.

Binding MOAD and PDBbind have similar goals to each other in the sense that both aim to provide binding data for biomolecular complexes archived in PDB, which is a key difference of the two databases from BindingDB. All three databases provide binding affinity information for protein-ligand complexes, but only a small fraction of protein-ligand affinity data in BindingDB have corresponding crystal structures in PDB. On the other hand, Binding MOAD and PDBbind do have some notable differences from each other. For example, whereas Binding MOAD considers only high-quality structures with a resolution of 2.5 Å or better, PDBbind covers all complexes regardless of the resolution. Instead, PDBbind compiles the refined and core sets to provide high-quality data (see Section PDBbind above). In addition, BindingDB focuses on protein-ligand complexes, but PDBbind has a broader coverage, including protein-ligand complexes as well as other types of complexes (e.g., protein-protein complexes).

Databases of drug information

DrugBank

DrugBank offers comprehensive information on more than 8000 small-molecule drugs and biotech drugs (Law *et al.*, 2014; Knox *et al.*, 2011; Wishart *et al.*, 2006, 2008). While the initial release of DrugBank provided information on selected U.S. Food and Drug Administration (FDA)-approved drugs and their targets, it has been expanding in the depth and breadth of its data and the current release (DrugBank 5.0) contains ~2000 FDA-approved (human and veterinary) drugs, ~1000 investigational drugs (in phase I, II, and III clinical trials), and ~5000 experimental drugs (experimentally shown to bind to specific proteins in humans as well as known bacterial, viral, and fungal pathogens). It also covers hundreds of withdrawn drugs, illicit drugs, and nutraceuticals. For each drug, DrugBank compiles a wide range of information, including their targets, metabolic enzymes, transporters, carriers, drug-drug and drug-food interactions, pharmacogenomic and pharmacoeconomic data, and many others. Because most of these data are manually curated by domain experts and biocurators, DrugBank serves as the source of reference drug data for many chemical databases such as PubChem, PharmGKB, and ChEBI.

Notably, DrugBank has a rich collection of drug metabolism information, including 1200 drug metabolites and 1300 drug metabolism reactions. In addition, a large amount of ADMET (absorption, distribution, metabolism, excretion and toxicity) data are recently added to DrugBank, including Caco2 cell permeability, blood-brain barrier permeability, human intestinal absorption levels, P-glycoprotein activity, CYP450 substrate preferences, renal transport activity, carcinogenicity, Ames test activity, human Ether-a-go-go Related Gene (hERG) activity, etc. DrugBank also provides reference mass spectrometry (MS) and NMR spectra of pure drugs and their metabolites, along with specialized tools for visualizing and searching these spectral data. These spectral data and tools are very useful for identification and/or quantification of compounds in biological matrices.

IUPHAR/BPS Guide to PHARMACOLOGY

The Guide to PHARMACOLOGY (GtoPdb) is a pharmacological information portal that provides expert-curated information on molecular interaction between drug targets and their selective ligands (Southan *et al.*, 2016; Pawson *et al.*, 2014). It was created from collaborative efforts between the International Union of Basic and Clinical Pharmacology (IUPHAR) and the British Pharmacological Society (BPS), by curating and integrating data from the IUPHAR-DB and the published BPS “Guide to Receptors and Channels” (GRAC) compendium.

The early versions of GtoPdb covered the G protein-coupled receptors (GPCRs), ion channels, and nuclear hormone receptors (NHRs) because many drug targets belong to these protein classes. However, the scope of GtoPdb has been expanded to other protein classes, including catalytic receptors, transporters, proteases, kinases, enzymes, etc., with the aim of capturing the likely targets of future medicines. While focused on human proteins, GtoPdb also contains information on mouse and rat orthologs because rodent binding data are most commonly encountered in scientific articles. For each target, GtoPdb provides selective ligands and their quantitative binding data (e.g., K_i , IC_{50} , or K_d), manually curated from scientific research articles. These ligands may be endogenous (e.g., metabolites, hormones, neurotransmitters, and cytokines) or exogenous (e.g., drugs, research leads, toxins, and probes). Currently, GtoPdb covers 2813 targets and 8900 ligands.

GtoPdb uses a unique curation strategy based on the collaboration between in-house curators and the IUPHAR Committee on Receptor Nomenclature and Drug Classification (NC-IUPHAR), which has a network of hundreds of domain experts organized into 60 subcommittees specialized in individual target families. These subcommittees guide target and ligand annotation in GtoPdb, by identifying key pharmacological properties of each target and its quantitative bioactivity data with important ligands. They also monitor de-orphanization of receptors (i.e., identifying new endogenous ligands). In addition, GtoPdb incorporates nomenclature recommendations from NC-IUPHAR. It also adopts and disseminates NC-IUPHAR-derived standards and terminology in quantitative pharmacology.

Pharmacogenomics Knowledge Base (PharmGKB)

The Pharmacogenomics Knowledge Base (PharmGKB) offers information on the impact of genetic variations on drug responses (Whirl-Carrillo *et al.*, 2012; Hernandez-Boussard *et al.*, 2008; Hewett *et al.*, 2002). It contains the relationships between drugs, diseases/phenotypes and genes involved in pharmacodynamics (PD) and pharmacokinetics (PK), extracted from literature using manual curation and natural language processing (NLP) techniques. Importantly, PharmGKB extracts from scientific publications the reported associations between gene variants (single-polymorphism or haplotype) and drug phenotypes, along with key study parameters such as the study size, population ethnicity, and statistics (e.g., *p*-values and odd ratios). In addition, it collects information on drug-centered pathways that contain the genes involved in the PD/PK of a particular drug. These pieces of information are used to create Very Important Pharmacogene (VIP) summaries that provide a concise overview of critical genes involved in drug response, with links to the literature, gene variant and haplotype details, and relevant drugs.

In PharmGKB, multiple annotations derived from different publications may exist for a given association between a single genetic variant and a drug phenotype. PharmGKB combines these annotations into a “clinical annotation” for that variant-drug-phenotype association, which essentially provides a genotype-based summary of the clinical impact of a genomic variant based on the information in PharmGKB. Each clinical annotation is scored for the strength of supporting evidence on a scale of 1A to 4, with 1A being the strongest evidence.

PharmGKB plays an important role in clinical implementation of pharmacogenomics knowledge. With the Pharmacogenomics Research Network (PGRN), PharmGKB participates in the Clinical Pharmacogenomics Implementation Consortium (CPIC), which publishes genotype-based drug guidelines to help clinicians optimize drug therapy using available genetic test results (Caudle *et al.*, 2014; Relling and Klein, 2011) (see the Relevant Websites section). Upon publication in a scientific journal after peer-review, these guidelines are simultaneously posted to PharmGKB with supplemental data and updates.

SIDER

In the drug discovery and development process, it is critical to identify potential undesired side effects of drug candidates as early as possible in order to reduce the late-stage attrition rate. Therefore, many attempts have been made to predict potential adverse drug reactions (ADRs) and elucidate the underlying biological mechanisms of the ADRs. In addition, several databases have been developed to provide information on ADRs and related drug targets (Juan-Blanco *et al.*, 2015; Cai *et al.*, 2015). One of them is the “Side Effect Resource” (SIDER) database, which currently contains 140,064 drug-ADR pairs between 1430 drugs and 5880 ADRs (Kuhn *et al.*, 2010, 2016). These data are extracted from drug labels and package inserts (including the Structured Product Labels from U.S. FDA) through a dictionary-based named entity recognition (NER) approach. SIDER also uses NLP to extract drug indications from the package inserts, which are used to identify false positives in the ADRs detected through NER.

Databases of chemical toxicity

Comparative Toxicogenomics Database (CTD)

The Comparative Toxicogenomics database (CTD) is a toxicogenomics resource that provides information on interactions between chemicals and genes/proteins and their relationships to diseases (Davis *et al.*, 2013, 2015, 2017). The core contents of CTD are chemical-gene, chemical-disease, and gene-disease interactions, extracted from scientific articles and manually curated by professional biocurators using controlled vocabularies and structured notation. This information is integrated with data from selected external resources, including Gene Ontology (GO) (Carbon *et al.*, 2017), Reactome (Fabregat *et al.*, 2016), NCBI Taxonomy and Gene, BioGRID (Chatr-Aryamontri *et al.*, 2017), and Medical Subject Headings (MeSH).

While the primary focus of CTD has been on environmental chemicals, it also contains a substantial amount of curated data from 88,000 articles that describe the toxic actions of pharmaceuticals on cardiovascular, neurological, hepatic and renal systems, thanks to the collaboration with Pfizer (Davis *et al.*, 2013).

In addition to curated interactions among the chemical-gene-disease triads, CTD also provides inferred relationships between them. For example, if a chemical has a curated interaction with a gene and if that gene has a curated association with a disease, the chemical is inferred to have a relationship with the disease and a putative link between them is created. This helps users to generate testable hypotheses. To assist users in navigating and prioritizing these inferences, CTD computes a ranking score for each inferred relationship, based on the topology of a local network, in which chemicals, genes, and diseases are represented as nodes connected

by edges corresponding to the curated interactions (King *et al.*, 2012). Integration with external annotations yields additional inferred relationships.

CTD currently contains more than 1.7 million manually curated interactions (> 1.5 million chemical-gene interactions, > 34 thousand gene-disease associations, and > 200 thousand chemical-disease associations) for 14,975 chemicals, 43,537 genes, and 6416 diseases extracted from 119,720 peer-reviewed scientific papers. It also has 20 million inferred gene-disease relationships and 1.9 million inferred chemical-disease relationships. In total, CTD offers more than 31 million toxicogenomic connections useful for analysis and hypothesis development.

Hazardous Substances Data Bank (HSDB)

The Hazardous Substances Data Bank (HSDB) at the NLM provides toxicological information for more than 5800 potentially hazardous chemicals, including heavy metal compounds, pollutants, herbicides, insecticides, radionuclides, solvents, pharmaceuticals, dietary supplements, venoms, and nanomaterials (Fonger *et al.*, 2014). Chemicals for HSDB record creation and update are nominated by NLM staff, scientific and regulatory agencies, advisory groups, and the public. These candidate chemicals are evaluated and selected by the HSDB chemical selection team, based on a number of considerations, including the level of toxicity, human and environmental exposure, the amount of production and use, and related factors such as regulatory status in the United States and other countries.

For the selected compounds, HSDB compiles various kinds of information, including (but not limited to) human exposure, industrial hygiene, emergency handling procedures, environmental fate, and regulatory requirements. These data are collected from a core set of books, government documents, technical reports, and journal articles. The collected information is peer-reviewed by the Scientific Review Panel (SRP), which consists of experts in major subject areas within the HSDB's scope.

The data contents in HSDB are labeled with one of three data quality tags: "PEER REVIEWED", "QC REVIEWED", and "UNREVIEWED". The data peer-reviewed by the SRP are tagged as "PEER REVIEWED". The "QC REVIEWED" tag means that a quality control review has been conducted by a HSDB senior reviewer or SRP subcommittee while a full peer review by SRP is pending. The "UNREVIEWED" tag indicates that the data has not been evaluated for scientific accuracy. Because this tag is used in the internal record building process, public HSDB data do not have the "UNREVIEWED" tag unless there is a special circumstance.

Databases in other categories

Human Metabolome Database (HMDB)

The Human Metabolome Database (HMDB) is a major metabolomics database, which offers comprehensive information on human metabolites, including their abundance, associated proteins, and disease-related properties (Wishart *et al.*, 2007, 2009, 2013). Currently, HMDB (version 3.6) contains detailed information on 52,658 metabolites, which can be classified into two groups: detected metabolites and expected metabolites. The detected metabolites are further divided into two groups: (1) detected and quantified and (2) detected but not quantified. The expected metabolites are those which could be or will be detected in the future, based on the current knowledge of human biochemistry along with human food and drug consumption patterns. Metabolites are further classified as being endogenous, microbial, drug derived, a toxin/pollutant, food derived, or different combinations of these.

The HMDB provides information on the experimentally determined concentrations of metabolites in various biofluids and/or tissues (e.g., cerebrospinal fluid, serum, urine, saliva) and tissues (e.g., prostate). Disease association and abnormal concentrations were manually curated from literature. In addition, it has reference NMR, tandem mass spectrometry (MS/MS), and gas chromatography-mass spectrometry (GC-MS) spectra. MS and NMR spectra were collected, assigned, and/or annotated by the HMDB curation team. Hundreds of additional annotated/assigned MS and NMR reference spectra were obtained from the BioMagResBank (Ulrich *et al.*, 2008), METLIN (Smith *et al.*, 2005; Tautenhahn *et al.*, 2012), and MassBank (Horai *et al.*, 2010). These spectral data are available for download as image files or in widely used spectral data exchange formats, such as JCAMP-DX (Davies and Lampen, 1993; Lampen *et al.*, 1994), nmrML, and mzML (Deutsch, 2008; Martens *et al.*, 2011), etc, which capture relevant spectral features, spectral collection conditions, assignments, and chemical structure information.

Chemical Entities of Biological Interest (ChEBI)

Chemical Entities of Biological Interest (ChEBI) at the EMBL-EBI is a free online dictionary of "small" molecular entities (Hastings *et al.*, 2013, 2016; De Matos *et al.*, 2010). The term "molecular entity" refers to "any constitutionally or isotopically distinct atom, molecule, ion, ion pair, radical, radical ion, complex, conformer, etc., identifiable as a separately distinguishable entity" (Degtyarenko *et al.*, 2008). While ChEBI focuses on small chemical compounds (either naturally-occurring or synthetic) that affect biological processes of living organisms, it excludes molecules directly encoded by the genome (e.g., nucleic acids, proteins and peptides derived from proteins by cleavage) as a rule.

The current release of ChEBI (Release 152) contains more than 50,000 fully curated entries with another ~50,000 entries that have not been processed yet. For each annotated entry, a wide range of manually curated data items are provided, including chemical structures and chemical structure representations (International Chemical Identifier (InChI) (Heller *et al.*, 2013, 2015), InChIKey, and simplified molecular-input line-entry system (SMILES) strings (Weininger, 1988, 1990; Weininger *et al.*, 1989)),

chemical names (IUPAC names, International Non-proprietary Names (INNs), brand names, and other synonyms), and literature citations. In addition, each entry is extensively cross-referenced to related records in external databases.

An important feature of ChEBI is that each entry in ChEBI is classified within the “ChEBI ontology”. It consists of two main subontologies: (1) a chemical entity ontology in which chemical entities are classified based on shared structural features and (2) a role ontology in which classifies entities based on their activities in biological or chemical systems or their use in applications. Through this ontological classification, ChEBI specifies the relationship between molecular entities (or classes of entities).

UniChem

Chemical information available in the public domain is scattered across many different databases. Identifying equivalent chemical entities from these resources is not a trivial task because individual resources adopt different data models, release schedules, structure standardization rules, chemical nomenclatures, etc. UniChem is a free compound identifier mapping service developed by EMBL-EBI to address this data integration issue (Chambers *et al.*, 2013, 2014; Hersey *et al.*, 2015). It contains standard InChIs (Heller *et al.*, 2013, 2015) for more than 145 million chemical structures stored in > 30 databases, along with pointers between these structures and chemical identifiers from all the individual databases. Therefore, UniChem is very useful to cross-reference equivalent chemical records between different databases.

Originally, UniChem produced mappings between chemicals in different sources on the basis of complete identity between their standard InChIs (i.e., only if their standard InChIs are completely identical) (Chambers *et al.*, 2013). However, this approach appeared too narrow and stringent for some purposes because stereoisomers, isotopes, and salts of otherwise identical molecules could not be related. For this reason, UniChem introduced a service called “Connectivity Search”, in which the equivalence between molecules can be determined at different levels of structural specification (Chambers *et al.*, 2014). This service exploits the layered structural representation of standard InChIs, by matching molecules on the basis of the complete identity of their connectivity layers and then comparing the remaining layers to check the stereochemical and isotopic differences. It also supports mixtures and salts, by using standard InChI sublayers.

UniChem is a highly automated system. When new data are loaded into one source, all links between this source and all the others are automatically calculated and immediately available. UniChem also provides users with a RESTful web service interface for programmatic access to its data.

Closing Remarks

In this article, several public chemical databases useful for cheminformatics and bioinformatics research have been described. Some of these databases like PubChem and ChemSpider contain a very large number of molecules (91 millions and 59 millions, respectively) and provide a wide variety of information, including chemical, physical, and spectral properties, pharmacology, toxicology, metabolism, safety and handling, environmental health and many others. Essentially, these databases are data aggregators, which collect and integrate information from various sources.

Other databases usually offer specialized information for a small number of compounds relevant to narrow focus areas. For example, ChEMBL, BindingDB, PDBbind, and Binding MOAD extract bioactivity data from scientific articles and/or patent documents. DrugBank contains manually curated information for FDA-approved and experimental drugs. GtoPdb provides information on the interaction between drug targets and their ligands, and PharmGKB focuses on pharmacogenomics aspects of drug response. SIDER collects information on the side effect of drugs. CTD and HSDB are specialized in toxicological information, and HMDB compiles metabolomics information. ChEBI provides ontology-based classifications of chemicals and UniChem deals with cross-reference information among different databases.

Although these databases often show substantial overlaps with each other in terms of the compound coverage as well as the type of information they provide, each database does have unique data contents, which can complement the information in other databases. While data exchange between different databases has become a very common practice, this also has raised serious concerns over quality control of public-domain chemistry data. For example, the lack of a standard in chemical structure representation has made individual database developers adopt different chemical structure standardization rules that suit their needs. As a result, it is not trivial to figure out which compound in one database is the same as a compound in another database, often leading to incorrect mapping between compounds from different databases.

Users of public chemical databases should be aware of potential data quality issues (Southan *et al.*, 2013; Kramer *et al.*, 2012; Hu and Bajorath, 2012; Muresan *et al.*, 2011; Tiikkainen *et al.*, 2013; Williams *et al.*, 2012; Williams and Ekins, 2011; Hersey *et al.*, 2015; Akhondi *et al.*, 2012; Fourches *et al.*, 2010; Tiikkainen and Franke, 2012; Williams, 2008b). Therefore, some important papers about the data quality issues are listed in the Further Reading section. In addition, this section contains papers about (1) programmatic access to selected databases (Kim *et al.*, 2015; Davies *et al.*, 2015; Swainston *et al.*, 2016); (2) Resource Description Framework (RDF)-formatted chemistry data for data exchange, sharing, and integration (Willighagen *et al.*, 2013; Jupp *et al.*, 2014; Fu *et al.*, 2015); and (3) commonly used chemical structure representations (Warr, 2011; Heller *et al.*, 2015; Weininger, 1988).

Biographical Sketch

Sunghwan Kim is a Staff Scientist at the National Center for Biotechnology Information (NCBI), National Library of Medicine (NLM), U.S. National Institutes of Health (NIH). As a computational chemist and cheminformatician, he is actively involved in the PubChem project, which develops and maintains a small-molecule database called PubChem. Specifically, his research has been focused on building and improving “PubChem3D,” which is PubChem’s chemical information resource derived from 3-dimensional (3-D) molecular structures. He holds a MSc in Inorganic Chemistry (from Hanyang University, South Korea) and a PhD in Physical Chemistry (from the University of Georgia at Athens).

Chemical Similarity and Substructure Searches

Nils M Kriege and Lina Humbeck, TU, Dortmund, Germany

Introduction

A fundamental concept in cheminformatics is the assumption that chemically similar molecules share similar bioactivities. Therefore, comparison of molecules and the determination of similarities between molecules is an important and often applied task for the identification and development of bioactive molecules (Humbeck and Koch, 2017). Many different methods and concepts have been developed to solve this essential task and it is crucial to understand and know what they are based on as similarity is not a rigid, globally defined or fixed property but rather reflects the perspective of the investigator. As with so many things in life, similarity is in the eye of the beholder.

Firstly, the molecules have to be represented. This can be achieved by a descriptor, a fingerprint or a structural formula. A descriptor is a number like the molecular masses of two molecules, a fingerprint is a vector representation and a structural formula is a molecular graph. The latter one is an intuitive as well as exact representation where vertices represent atoms and edges represent bonds. Secondly, one can discriminate between different types of searches. For example there are cases where one wants to find the exact same structure, only molecules which contain the query molecule as a substructure or molecules sharing the same fragment. In other cases only molecules that are somehow similar are of interest.

These similarity based concepts can be further divided into similarity based on substructures, pharmacophores, fingerprints, shapes, biological activities and so on. Two molecules that share a similar molecular surface (shape) are expected to be similar. A fingerprint could be a bit representation of the presence or absence of fragments and two molecules with similar fingerprints are also expected to be similar. A pharmacophore is a three dimensional arrangement of molecular features that is important for the interaction with the protein target (Guner, 2002). The three dimensional molecular graph of a query molecule is compared to this spatial arrangement and the molecule fulfills this pharmacophore, if its feature arrangement based on its graph is also similar. The search for a largest possible substructure which is present in two molecules is called MCS (Maximum Common Substructure) search. Nevertheless, often different kinds of representations and searches are used together.

In the following some specific concepts are presented to get an idea of the importance of chemical similarity. Quantitative Structure-Property Relationships (QSPR) and Quantitative Structure-Activity Relationships (QSAR) are two such concepts. One of the first QSPR analyses was done in 1947 and included the Wiener Index as description of molecular properties to predict the boiling points of alkane molecules (Wiener, 1947). A more specialized property – the bioactivity – is analyzed using corresponding QSAR (Leach and Gillet, 2007). As described, it might be valuable to compare the shapes of molecules. Therefore, tools like ROCS (Hawkins *et al.*, 2007) or ShaEP (Vainio *et al.*, 2009) can be used. One can also group molecules regarding their target proteins (Keiser *et al.*, 2007) or correlate descriptors with certain properties to guide synthesis to optimized molecules.

Another often discussed approach are privileged scaffolds, which are scaffolds – meaning same core substructures of different molecules – that show activities on different protein families. Hence, they are interesting starting points for drug design projects and additionally close to the medicinal chemists view of molecules. A tool which enables a scaffold focused view of molecular databases is Scaffold Hunter (Schäfer *et al.*, 2017). One also has to be aware of substructures that interfere with assay systems termed PAINS (Pan Assay Interference Substances) (Baell *et al.*, 2013) or that are unspecific destabilizers of proteins, e.g. aggregators (Irwin *et al.*, 2015).

As mentioned above the topic of similarity and comparability is closely related to the challenge to properly represent the molecule. Often molecules are represented as vectors which make them applicable to a bunch of methods, e.g., QSAR approaches. However, this representation loses information, e.g., regarding the connectivity and structure of molecules. In contrast a graph based representation is closer to the intuitive chemical understanding of molecules. Unfortunately, efficient algorithms are needed to keep the increased calculation times small. In this article we introduce some graph based algorithms to compare molecules and discuss their applications.

Background and Fundamentals

By the middle of the nineteenth century the growing knowledge about chemical atoms and how they combine to form larger structures led to meaningful diagrams, which can be seen as early applications of *graph theory* (Biggs *et al.*, 1986). This section introduces into graph theory as well as molecular graph representation and summarizes graph theoretical fundamentals using modern terms and notation.

Graph Theory

A graph $G = (V, E)$ consists of a finite set $V(G) = V$ of *vertices* and a finite set $E(G) = E$ of *edges*, where each edge connects two distinct vertices. We denote an edge connecting a vertex u and a vertex v by uv or vu , where both refers to the same edge. A *path* of length n is

Fig. 1 Examples of subgraphs and their properties, where gray vertices and edges are not contained in the subgraph.

a sequence of vertices $(v_0, \dots, v_n)$ such that $v_i v_{i+1} \in E$ for $0 \leq i < n$. A graph is *connected* if at least one path between any two vertices exists and is *disconnected* otherwise. A *cycle* is a path of length at least 3 with no repeated vertices except $v_0 = v_n$. A graph $G' = (V', E')$ is a *subgraph* of a graph $G = (V, E)$, written $G' \subseteq G$, if $V' \subseteq V$ and $E' \subseteq E$. A subgraph $G' \subseteq G$ is said to *span* G if $V(G') = V(G)$. Let $V' \subseteq V$ and $E' = \{uv \in E \mid u, v \in V'\}$, then $G' = (V', E')$ is said to be a (*vertex-*)*induced* subgraph of G and is denoted by $G[V']$. Let $E' \subseteq E$ and V' be the set of vertices that appear as endpoint of at least one edge in E' , then $G' = (V', E')$ is said to be an *edge-induced* subgraph of G and denoted by $G[E']$. An edge is a *bridge* if it is not contained in any cycle. A *block* is a maximal connected subgraph that does not contain a bridge. A subgraph $G' \subseteq G$ is *block and bridge preserving* (BBP) if (i) each bridge in G' is a bridge in G , (ii) any two edges in different blocks in G' are in different blocks in G . Fig. 1 shows examples of different subgraphs.

An *isomorphism* between two graphs G and H is a bijection $\psi: V(G) \rightarrow V(H)$ such that $uv \in E(G) \Leftrightarrow \psi(u)\psi(v) \in E(H)$ for all $u, v \in V(G)$. Two graphs G and H are said to be *isomorphic*, written $G \cong H$, if an isomorphism between G and H exists. A *subgraph isomorphism* from a graph G to a graph H is an isomorphism between G and a subgraph $H' \subseteq H$. A *common subgraph isomorphism* between G and H is an isomorphism between subgraphs $G' \subseteq G$ and $H' \subseteq H$.

A graph is called *complete* if every pair of distinct vertices is adjacent. Given a graph $G = (V, E)$, a *clique* is a subset of vertices $C \subseteq V$ such that $G[C]$ is a complete graph. A clique C is said to be *maximum* if there is no clique C' with $|C| < |C'|$. A *tree* is a connected graph containing no cycles. The following concepts intuitively allow to measure how “tree-like” a graph is. A graph G is called a *k-almost tree* if $|E(B)| < |V(B)| + k$ is satisfied for every block B in G . A graph is said to be a *partial k-trees* if it has a tree decomposition of width at most k (see, e.g., Brandstadt et al., 1999, for details). The partial 2-trees are also called *series-parallel graphs*. A graph is *planar* if it admits a drawing in the plane such that no two edges cross; it is called *outerplanar* if it admits such a drawing with every vertex lying on the boundary of the unbounded region.

Graph Representations of Molecules

The *molecular graph* of a chemical compound is the graph, where the vertices represent the atoms and the edges the bonds of the molecule. The vertices of a molecular graph are typically annotated by the element symbols of the atoms they represent and the edges by the bond types. Additional information like a more differentiated atom type classification or 3D coordinates may be used also. An isomorphism between molecular graphs typically has to preserve such labels. Hydrogen atoms may or may not be represented explicitly. Molecular graphs exhibit several characteristic properties.

- The distribution of vertex and edge labels is non-uniform, e.g., the majority of vertices represent carbon atoms and is labeled by ‘C’.
- The maximum degree of molecular graphs is bounded by a small constant (≤ 4 with very few exceptions) as a result of the atom valency.
- The vast majority of molecular graphs are planar, and most are even outerplanar (Horváth et al., 2010). Here, we mean planar in a graph theoretical sense, while otherwise a molecule typically is considered planar if all atoms are on the same plane w.r.t. their 3D arrangement.
- Molecular graphs typically are tree-like. Yamaguchi et al. (2003) computed the tree width of 9712 molecular graphs derived from the LIGAND database (Goto et al., 2002) and found that there is only one graph with tree width 4, while all other have tree width at most 3. Actually, 19.4% of the graphs are trees and 95% are series-parallel graphs.

These properties can be exploited in order to obtain algorithms, which solve subgraph isomorphism problems efficiently for molecular graphs.

Apart from this natural representation so-called *reduced graph* models have been developed, which represent groups of connected atoms by a single vertex (see Birchall and Gillet, 2011, and references therein). Reduced graphs typically contain only a fraction of the vertices and edges of molecular graphs, but may still contain cycles. Simplifying the representation further, Rarey and Dixon (1998) proposed to represent molecules by trees, which encode their hydrophobic fragments and functional groups.

Substructure Search

Given a data set of molecules and a query structure, the *substructure search problem* is to determine the subset of molecules that contain the query structure. Hence, this task requires to decide for each molecular graph G in the data set whether a subgraph isomorphism from the query graph Q to G exists. The subgraph isomorphism problem is well-studied and algorithms have been developed in cheminformatics since the 1950s (Barnard, 1993). Experimental evaluations in the 1980s suggested that the backtracking algorithm by Ullmann (1976) achieves a superior performance to these early algorithms (see Willett, 1999). Since then backtracking algorithms were heavily applied in practice and have been further enhanced. These approaches extend a partial mapping from the vertices of Q to the vertices of G step-by-step and perform backtracking if the current mapping cannot be completed. Most approaches maintain for every vertex of Q a set of eligible candidate vertices of G , which is filtered whenever the mapping is extended. Moreover, the ordering, in which the mapping is extended is a crucial component of this type of algorithm and has an important effect on the running time. The early algorithm by Ullmann (1976) uses elaborate candidate filtering referred to as *refinement*. Later computational less demanding filtering techniques in combination with certain vertex orderings were shown to be more efficient for practical instances. Cordella *et al.* (2004) proposed the VF2 algorithm and experimentally showed it to outperform Ullmann's algorithm on instances from pattern recognition. More recently, it was shown that straight-forward backtracking approaches similar to VF2, which do not manage candidate sets explicitly, but exploit the low degree and diverse vertex labels of molecular graphs, are highly efficient for molecular graphs in practice (Kriege, 2009; Klein *et al.*, 2011; Ehrlich and Rarey, 2012). Moreover, Ullmann (2011) proposed an improved version of his algorithm relying more on search and less on a demanding refinement procedure.

Although the subgraph isomorphism problem is NP-complete for general graphs, the above mentioned backtracking algorithms with exponential worst-case running time are convenient for molecular graphs. Therefore, polynomial-time algorithms, which exist for many graph classes (Marx and Pilipczuk, 2014) (including almost all molecular graphs) are of little practical relevance. However, since chemical databases contain millions of molecules and must be able to answer a large number of substructure queries within a short response time, indexing techniques have been developed. In a preprocessing step an index data structure is build, which then typically allows to process a query as follows. First, in the filtering step the existence of a subgraph isomorphism is ruled out for most of the molecules. Then, only the remaining candidates are tested by a subgraph isomorphism algorithm in the subsequent verification step. We refer the reader to Barnard (1993), and references therein for more details on implementations in chemical information systems and to Klein *et al.* (2011), and references therein for more recent approaches studied in the broader field of graph indexing and mining.

Maximum Common Subgraph Problems

The identification of substructures which two molecules share is related to the maximum common subgraph problem. This problem is independent of the used graph model and is defined as follows. Given two graphs, determine the maximum size of a common subgraph isomorphism between them. This leads to several problem variants, which differ w.r.t. the definition of a size function and the types of allowed subgraphs. The considered subgraphs may be (i) required to be connected, or (ii) allowed to be disconnected. Moreover, they may be required to preserve ring systems, i.e., to be block and bridge preserving, and may be required to be vertex- or edge- induced. This already leads to twelve possible variants, which are summarized in Table 1 together with an adequate size function and a name commonly used (although the terminology in the literature is far from being consistent).

All the above mentioned variants of the maximum common subgraph problem are NP-hard in general graphs. It is suspected that no polynomial-time algorithms for such problems exist. However, several special cases for restricted graph classes are known that allow to obtain polynomial-time algorithms. There is a complex interplay between graph classes, the properties of the desired common subgraph and the complexity of the problem, which is yet not fully understood. Table 2 summarizes known results that are particularly relevant for molecular graphs.

We review classical techniques in Sections "Reduction to the Clique problem" and "Direct branch-and-bound approaches" and summarize polynomial-time algorithms of practical relevance in Section "Polynomial-time algorithms for restricted graph classes".

Algorithms

As a consequence of the practical relevance of the problem maximum common subgraph algorithms have been studied intensively in cheminformatics and other disciplines like pattern recognition (Conte *et al.*, 2004). Since maximum common subgraph

Table 1 Variants of the maximum common subgraph problem with commonly used size functions. In addition, each variant can be restricted to common subgraphs that are connected or block and bridge preserving

Name: Maximum...	Abbrev.	Size	Induced	Connected	Preserve rings
Common Subgraph	MCS	$ V(G) + V(E) $	–	MCCS	BBP-MC(C)S
Common Induced Subgraph	MCIS	$ V(G) $	vertex	MCCIS	BBP-MC(C)IS
Common Edge Subgraph	MCES	$ E(G) $	edge	MCCES	BBP-MC(C)ES

Table 2 Summary on complexity results for the maximum common induced subgraph problem and its variants. Note that the graph classes are related as follows: trees $\subset$ outerplanar graphs $\subset$ series-parallel graphs $\subset$ partial k -trees; and trees $\subset$ k -almost trees $\subset$ partial k -trees (Bodlaender, 1986); (Δ -bounded – the maximum degree is bounded by a constant; * – the result was originally shown for the edge-induced variant)

Input graph class	Constraint	Complexity
Trees	–	NP-hard (Brandenburg, 2000)
	connected	P (Matula, 1978; Droschinsky et al., 2016)
k-almost trees	connected	NP-hard for any $k \geq 1$ (Akutsu, 1993)
Δ -bounded	connected	P (Akutsu, 1993)
Outerplanar graphs	connected	NP-hard (Syslo, 1982)
	biconnected	P (Droschinsky et al., 2017)
	connected, BBP	P (Droschinsky et al., 2017)
Δ -bounded	connected	P (Akutsu and Tamura, 2013)*
Series-parallel graphs	biconnected	P (Kriege and Mutzel, 2014)
	connected, BBP	P (Kriege et al., 2014, 2018)
Partial k-trees	j -connected, $j < k$	NP-hard for any $k \geq 1$ (Brandenburg, 2000)
	k -connected	Open for $k > 2$
Δ -bounded, $k = 11$	connected	NP-hard (Akutsu and Tamura, 2012b)
Δ -bounded	connected	Open for $k \in \{2, \dots, 10\}$

problems are NP-hard unless the input graphs are heavily restricted, general purpose algorithms commonly used in practice have an exponential worst-case running time. These algorithms typically rely on branch-and-bound techniques to eventually solve the problem to optimality, but still differ in their approach. We group these techniques accordingly.

Reduction to the Clique problem

The most common approach in practice is to exploit the one-to-one correspondence between common induced subgraph isomorphisms of the input graphs and cliques in their association graph (also *compatibility graph* (Koch, 2001; Durand et al., 1999), *product graph* (Koch, 2001; Cazals and Karande, 2005), *derived graph* (Barrow and Burstall, 1976), or *weak modular product graph* (Hammack et al., 2011)), which was described by Levi (1973) and later by Barrow and Burstall (1976). For two graphs $G=(V, E)$, $H=(V', E')$, their *association graph* is denoted by $G \nabla H = (\mathcal{V}, \mathcal{E})$, where $\mathcal{V} = V \times V'$ and $\mathcal{E}$ contains an edge connecting (u, u') , $(v, v') \in \mathcal{V}$ if $u \neq v$, $u' \neq v'$ and $uv \in E \Leftrightarrow u'v' \in E'$. Each vertex of the association graph represents a mapping of a vertex of G to a vertex of H . Two vertices in the association graph are adjacent if their corresponding vertex mappings are compatible, i.e., the involved vertices exhibit the same relation (adjacent or non-adjacent) in both graphs.

Levi (1973) has shown that two graphs G and H have a common induced subgraph with k vertices if and only if there is a clique with k vertices in $G \nabla H$. Further, there is a one-to-one correspondence between the common induced subgraph isomorphisms and cliques in the association graph. Let $C = \{(v_1, v'_1), \dots, (v_k, v'_k)\} \subseteq \mathcal{V}$ be a clique in $G \nabla H$, $U = \{v_1, \dots, v_k\} \subseteq V(G)$ and $U' = \{v'_1, \dots, v'_k\} \subseteq V(H)$, then $\psi(v_i) = v'_i$, for $i \in \{1, \dots, k\}$, is an isomorphism between $G[U]$ and $H[U']$. Consequently, the maximum cliques in the association graph correspond to the isomorphisms between maximum common induced subgraphs. Note that there may be different isomorphisms acting on the same sets of vertices of the two input graphs.

This relation allows to reduce the MCIS problem to the maximum clique problem. There is a multitude of algorithms devised for maximum clique detection, see the surveys by Pardalos and Xue (1994) and Bomze et al. (1999) for an overview. The algorithm by Bron and Kerbosch (1973) enumerates all maximal cliques and is often used in practice (see, e.g., Koch, 2001). If one is only interested in an arbitrary maximum clique or just the size of a maximum clique, branch-and-bound techniques are used to speed up the search. These essentially allow to ignore unfruitful branches in the search tree, whenever an upper bound of the possible solution size within the branch drops below the best known current solution. Consequently, these techniques benefit from heuristics to find a good solution early. One example of these algorithms is due to Wood (1997), which is employed by Stahl et al. (2005). Conte et al. (2007) performed an extensive experimental comparison including several clique detection algorithms. However, the study does not reveal clear evidence for one algorithm being preferable in practice.

In order to preserve labels of molecular graphs with this approach, it suffices to create a vertex in the association graph only if the vertex labels of the input graphs agree (and analogously for edges and edge labels). More generally, a similarity measure on the vertex and edge labels can be defined, which leads to a weighted association graph in which the clique of maximum weight corresponds a maximum common subgraph isomorphism w.r.t. the weight function (Barrow and Burstall, 1976).

Finding edge-induced common subgraphs. Nicholson et al. (1987) proposed a general reduction from MCES to MCIS based on the above approach, which was later applied on various occasions (Tonnelier et al., 1990; Durand et al., 1999; Koch, 2001). Instead of directly creating the association graph of the two input graphs, the association graph of their line graphs is created. The *line graph* $L(G)$ of a graph G is the graph with vertex set $V(L(G)) = E(G)$, in which two vertices are adjacent if and only if the two corresponding edges are adjacent in G . Obviously, two isomorphic graphs have isomorphic line graphs. A classical result states that, except for the graphs depicted in Fig. 2, the reverse holds as well.

Fig. 2 The non-isomorphic graphs (a) and (b) have the same line graph (c).

Theorem: (Whitney, 1932). Given two connected graphs G and H . If $L(G) \simeq L(H)$ then $G \simeq H$, unless $G \simeq K_{1,3}$ and $H \simeq K_3$ or vice versa (The result was originally formulated without the notion of line graphs and instead directly relates graph isomorphism to edge isomorphism. An *edge isomorphism* is a bijection between edges such that any two edges are adjacent in one graph if and only if the associated edges in the other graph are adjacent).

The single exception is referred to as ΔY -exchange (Raymond and Willett, 2002a; Raymond et al., 2002b) or triode-triangle interchange (Durand et al., 1999).

The family of line graphs is closed under vertex removal, i.e., each induced subgraph of a line graph again is a line graph. Furthermore each vertex-induced subgraph of $L(G)$ directly corresponds to an edge-induced subgraph of G and vice versa. Based on this idea common edge subgraphs can be detected by finding cliques in $L(G) \nabla L(H)$, if ΔY -exchanges are handled adequately: For a common induced subgraph K_3 between two line graphs, it must be verified that the corresponding edge-induced subgraphs in the original graphs are either both K_3 or both $K_{1,3}$. The check can be incorporated in the clique detection algorithm, but the same idea also can be used for other exact MCIS algorithms. The transformation can be extended to cope with labeled graphs by creating labeled line graphs (Raymond et al., 2002b). Tonnelier et al. (1990) as well as Durand et al. (1999) and later Koch (2001) directly define an equivalent edge association graph without using the notion of line graphs.

Finding connected common subgraphs. The above approach can be adapted to find connected common subgraphs. Tonnelier et al. (1990) considered the problem of enumerating all maximal connected common edge subgraph isomorphisms between two graphs G and H . A naïve approach is to enumerate all maximal cliques in the association graph $L(G) \nabla L(H)$ and to keep only the connected solutions. Koch (2001) avoids the exhaustive enumeration by directly restricting the search space. The key idea is to distinguish between two types of edges in the association graph: Edges that are due to common adjacencies are called *c-edges*, all other edges represent the absence of adjacency in both graphs and are referred to as *d-edges*. A clique C in an association graph A is called *c-clique* if $A[C]$ has a spanning subgraph induced by *c-edges*. Koch (2001) showed that a clique in the association graph corresponds to an isomorphism between common connected edge subgraphs if and only if it is a *c-clique*. Based on this observation the algorithm by Bron and Kerbosch (1973) is extended to find only *c-cliques*, which reduces the solution space considerably. Some flaws in the algorithm were later corrected by Cazals and Karande (2005).

Direct branch-and-bound approaches

McGregor (1982) proposed an early branch-and-bound algorithm for MCES, which has been used for classifying chemical reactions (McGregor and Willett, 1981). The approach incrementally extends an initially empty partial mapping between $V(G)$ and $V(H)$, where at each step the i -th vertex of G is mapped to a vertex of H or is omitted from the correspondence. The generated partial mappings form a tree with the empty mapping represented by the root, and children extending the mapping of their parent by an additional vertex pair. In order to reduce the search space no further extension is performed when the size of a total solution can be foreseen not to surpass the best solution found so far. By this means unfruitful branches are cut-off. Therefore, heuristics for finding good solutions early strengthen the effect. Krissinel and Henrick (2004) improved McGregor's algorithm by adding extensions in a prescribed ordering and refining the set of possible extensions, which strengthens pruning. Such branch-and-bound optimizations are an integral part of constraint programming approaches, see Section "General purpose solvers". The algorithm has been used for searching the EBI-MSD ligand database (Boutselakis et al., 2003). The refinement procedure is inspired by a classical subgraph isomorphism algorithm due to Ullmann (1976). Cao et al. (2008) proposed a branch-and-bound approach to MCIS inspired by the VF2 subgraph isomorphism algorithm (Cordella et al., 2004), which involves a new ordering and bound based on maximum bipartite matching. Moreover, the approach allows to constraint the number of connected components of the common subgraph.

General purpose solvers

Constraint programming (CP) is a general approach to solve combinatorial problems, which are stated by a set of variables allowed to take values from a predefined domain and a set of constraints which must be satisfied by a solution. CP solvers typically follow an elaborated branch-and-bound approach. Vismara and Valery (2008) formulated two explicit CP models for MCCES, one inspired by the methods detailed in Section "Reduction to the Clique problem", and an original one based on a subdivision graph. The resulting problem again corresponds to a variant of the clique problem in a product graph with additional constraints. Ndiaye and Solnon (2011) proposed improved CP models for MCIS and MCES. In a recent experimental comparison McCreesh et al. (2016) showed that clique-based approaches for MCIS and MCCIS remain competitive with state-of-the-art CP solvers when using modern clique detection algorithms, in particular for labeled graphs. Moreover, maximum common subgraph problems have been formulated as integer linear programs (see Manić et al., 2009; Bahiense et al., 2012; Piva and de Souza, 2012). These approaches support to incorporate additional side constraints easily, but are not yet competitive regarding running time with clique-based algorithms (Bahiense et al., 2012).

Polynomial-time algorithms for restricted graph classes

Polynomial-time algorithms for MCCIS/MCCES in trees have been pioneered by J. Edmonds and Matula in the 1960s. They rely on solving a series of maximum bipartite matching instances (Matula, 1978). Only recently it has been shown by Droschinsky *et al.* (2016) that the approach can be implemented in cubic time. Akutsu (1993) showed that MCCES in k -almost trees is NP-hard for any $k \geq 1$, but can be solved in polynomial time in almost trees of bounded degree. Moreover, MCCIS can also be solved in polynomial time when one of the input graphs is a bounded-degree partial k -tree and the other is a connected graph with a polynomial number of possible spanning trees (Yamaguchi *et al.*, 2004). Solving BBP-MCCES in outerplanar graphs can be achieved in polynomial time (Schietgat *et al.*, 2013); the same holds for BBP-MCCIS in outerplanar (Droschinsky *et al.*, 2017) and series-parallel graphs (Kriege *et al.*, 2014, 2018; Kriege and Mutzel, 2014). By non-trivial modification of an algorithm for BBP-MCCES Akutsu and Tamura (2012a, 2013) proved that MCCES in outerplanar graphs of bounded degree is polynomial-time solvable. Moreover, Akutsu and Tamura (2012b) have shown that MCCIS and MCCES both are NP-hard in vertex-labeled partial 1-trees of bounded degree. Kann (1992) studied the approximability of maximum common subgraph problems and Abu-Khzam (2014); Abu-Khzam *et al.* (2015, 2017) their parametrized complexity.

Most of the above mentioned results focus on the theoretical complexity and are not promising for practical applications. However, the BBP-MCCIS and BBP-MCCES algorithms have been implemented and applied to molecular graphs in practice. The BBP-MCCES approach by Schietgat *et al.* (2013) runs in $\mathcal{O}(n^4)$ time (Different worst-case bounds have been provided over time in consecutive publications: Starting with $\mathcal{O}(n^7)$ (Schietgat *et al.*, 2007), then $\mathcal{O}(n^5)$ (Schietgat *et al.*, 2008; Schietgat, 2010) and finally $\mathcal{O}(n^2 \sqrt{n})$ (Schietgat *et al.*, 2013). However, it has been shown that the analysis is flawed and the algorithm allows no better bound than $\mathcal{O}(n^4)$ (Droschinsky *et al.*, 2016).) and was shown to outperform the direct backtracking algorithm by Cao *et al.* (2008) in terms of running time in practice (Schietgat, 2010; Schietgat *et al.*, 2013). The BBP-MCCIS of Droschinsky *et al.* (2017) runs in $\mathcal{O}(\Delta n^2)$ time in outerplanar graphs on n vertices with maximum degree Δ and, thus, has a quadratic time complexity in molecular graphs. Experimentally, the technique is shown to outperform the BBP-MCCES approach by Schietgat *et al.* (2013) by orders of magnitude and allows to structurally compare drug-like molecular graphs in the range of a few milliseconds.

Heuristic algorithms

Some applications have strict constraints on running time, but do not require an accurate solution. In this case heuristic algorithms are applicable, which quickly compute a possibly non-optimal solution. We refer the reader to Englert and Kovács (2015), and references therein for heuristic algorithms. Note that the branch-and-bound approaches mentioned above may benefit from heuristics which find good solution quickly.

Variations of the Maximum Common Subgraph Problem

Fuzziness in the detection of maximum common subgraphs is often mentioned as a possible improvement over the strict matching rules (see, e.g., Sheridan and Miller, 1998; Raymond *et al.*, 2003; Hattori *et al.*, 2003). The above mentioned algorithms typically already allow, or can be adapted, to take this into account. The *multiple maximum common subgraph problem* asks for the maximum common subgraph of more than two input graphs. The problem already has been studied by Varkony *et al.* (1979), later by Bayada *et al.* (1992) and more recently by Hariharan *et al.* (2011) and Dalke and Hastings (2013). When large diverse data sets are considered, their common subgraph typically consists of small disconnected fragments, which are not meaningful. Therefore, the *frequent subgraph mining problem* asks for subgraphs that are contained in at least a certain percentage of the data set. This problem and several variants have been studied extensively, see, e.g., Cheng *et al.* (2010).

Applications

Every scientist working with molecules has for a certainty applied common substructure searches based on a maximum common subgraph. In general there are two major application domains for small molecule similarity searches and structure comparisons: prediction/identification and clustering. The former relies on the assumption that the properties of similar structures are similar, which enables the prediction of a property unknown for the molecule of interest but known for a similar one. In the latter application domain a segmentation of a dataset is of interest, e.g., to investigate the diversity. A good overview about possible applications can be found in Humbeck and Koch (2017). In the following some softwares will be mentioned for identification or prediction purposes and clustering tasks. A special open source software called *small molecule subgraph detector* was developed by Rahman *et al.* (2009). It includes different algorithms and chooses the most appropriate one by analyzing the input structures. The software allows to take chemical knowledge into account and finds best solutions w.r.t. atom type match and bond sensitivity.

Identification of Similar Molecules and Prediction of Properties

Raymond *et al.* (2002b) proposed RASCAL for the calculation of graph similarities based on MCES. The approach consists of an initial screening to decide quickly if a certain minimum similarity cannot be reached. Otherwise an elaborated MCES algorithm based on the approach described in Section "Reduction to the Clique problem" is employed, which uses a tailored clique detection

algorithm and exploits symmetries. The approach incorporates results of a long line of research in one MCES algorithm and employs domain-specific heuristics (Raymond *et al.*, 2002a). Similarly, Marialke *et al.* (2007) proposed *graph-based molecular alignment*, where the common subgraph not necessarily has to preserve adjacencies, but the shortest-path distances between atoms. This approach assures consistent arrangements of connected components.

Hartenfeller *et al.* (2012) developed a method which compares molecules using a graph representation to predict similar bioactivity. They collate *in silico* synthesized molecules with known bioactive molecules for the *de novo* design of molecules with similar bioactivity. Furthermore, they use three interesting approaches: A graph representation of the pharmacophoric features of the molecule, reduced graphs and a difference in feature count corrected Tanimoto similarity measure. Although they use a graph representation they do not use MCS algorithms for comparison. Algorithms based on MCS for virtual screening purposes are developed by Lešnik *et al.* (2015), Vainio *et al.* (2009) and Droschinsky *et al.* (2017). The first is called LiSiCA and uses a maximum clique algorithm to detect two and three dimensional similarities of molecular graphs. In contrast to the representation used by Hartenfeller *et al.* (2012) atom types instead of features are modeled by vertices. A product graph is generated and the maximum clique gets detected. The second approach, ShaEP, as well as LiSiCA works with a three dimensional representation, but uses electrostatical potentials and a local shape descriptor as vertex labels, which are not coincident with the heavy atoms of the molecule. Furthermore, they generate a completely connected graph and use the backtracking algorithm of Krissinel and Henrick (2004). ShaEP can also be used for the alignment of molecules.

Substructure searches are often applied to query large databases. For example PubChem supports this kind of approaches for the identification of molecules in their database that contain a molecule drawn on their webpage as substructure. This allows determining other molecules with, e.g., known bioactivity to get a first impression about the possible bioactivity profile of the query molecule.

Classification of Datasets

Due to the high complexity and long run time, clustering of datasets is often based on fingerprint based similarity. However, with increasing computational power and the development of sophisticated algorithms, molecular clustering based on graph representation arouse great interest. Schäfer and Mutzel (2017), for example, present a frequent subgraph based clustering approach termed StruClus including the identification of cluster representatives. Thus, the clustering is chemically intuitive and comprehensible. As the algorithm scales linearly with the dataset size it is capable of clustering datasets of tens of millions of molecules and therefore meets the challenges of ever growing (*in silico*) databases.

A clustering method based on MCES was proposed by Stahl *et al.* (2005) and introduced a similarity measure with penalty terms for inconsistent arrangements of the connected components of the common subgraph in the input graphs. The approach is shown to be able to produce clusterings of molecules which are in a better alignment with their target classes than previous common subgraph or fingerprint based approaches.

Another solution is given by Gardiner *et al.* (2007). They only focus on finding representatives of clusters by finding MCES using the RASCAL algorithm in a non-hierarchically preclustered dataset. The performance is improved by using reduced graphs, where functional groups are represented by a single vertex.

Results and discussion

The general suitability of graph based similarity and structure comparisons was demonstrated in many applications. Nevertheless, one has to choose an appropriate algorithm for a given task and attention should be paid to the graph representation of molecules. Vertices and edges may have different meanings and weighting may be possible. Moreover, reduced graph models allow for more efficient maximum common subgraph computations. Another critical point are the applied similarity or distance measures. Raymond and Willett (2002b) give an overview about common measures and present some intuitive similarity measures between molecules that can be defined on the basis of the size of their maximum common subgraph.

Typically maximum common subgraph algorithms are utilized as a subroutine in more complex applications like clustering. It depends on the application which type of algorithm is most suitable. If it is acceptable to trade accuracy for running time, heuristics may provide an adequate solution. Well-engineered exact algorithms have been developed, which solve the maximum common subgraph problem for most pairs of graphs within milliseconds, but are reported to take a very long time for few tough instances (Stahl *et al.*, 2005). The recent development of exact polynomial-time algorithms for restricted graph classes constitutes a step to overcome this problem. Yet further progress in this direction has to be made to obtain generally applicable algorithms.

Binding Site Comparison – Software and Applications

Christiane Ehart and Tobias Brinkjost, TU Dortmund University, Dortmund, Germany

Oliver Koch, Technical University of Dortmund, Dortmund, Germany

© 2019 Elsevier Inc. All rights reserved.

Introduction

The automated comparison of binding sites can provide useful insights into enzyme function, evolutionary relationships, poly-pharmacology, off-target effects and can assist in drug repurposing. Therefore, it has become a valuable tool especially in medicinal chemistry during the process of drug discovery. Another possible application domain is the functional characterization of novel binding sites by a comparison against already annotated and characterized ligand cavities. Recent scientific publications demonstrate that binding site similarity is by no means as obvious as one might expect, i.e., cavities of functionally and structurally distinct proteins might show a high similarity (Ehart *et al.*, 2016). Usually, the focus is on evolutionary related proteins by comparing protein structures or sequences. This strategy completely dismisses the possibility that unrelated proteins could bind similar ligands. Some very recent publications focus on the impact of local protein similarities on protein function (Garma *et al.*, 2016; Mudgal *et al.*, 2017). They underpin the general observation that a similar fold does not necessarily result in a similar function whereas a common function can be fulfilled by proteins with different folds. Therefore, the comparison of the binding site of interest against a data set of diverse binding sites might unravel some disregarded similarities. Nevertheless, it has to be stated that proteins binding to similar ligands or sharing a common function do not necessarily share a similar small molecule binding site (Barelir *et al.*, 2015).

Encouraged by a variety of useful applications, a multitude of binding site comparison tools were developed. They can be classified by the way the binding site is modeled, the comparison algorithm, or the similarity metric used for binding site similarity ranking. Binding site modeling is of special interest for the choice of the appropriate method according to the particular problem. Therefore, the first part of this article presents software with a special focus on binding site modeling. The second part is dedicated to the model principles and corresponding algorithms for binding site comparison explaining the different approaches in more detail. Finally, four examples for the impact of binding site comparison are discussed. The chosen problems illustrate that tools which are based on rather different binding site modeling, comparison, and similarity scoring concepts led interesting findings in the past. Therefore, the combination of various tools – also those not presented herein – might prove beneficial for a certain application.

A summary of all methods and their characteristics presented herein can be found in Table 1. The number of published tools is considerably large. Hence, only a small subset of software tools, which were successfully applied in various scientific projects and are available as standalone software, are discussed in this article. Additionally, we decided to exclusively introduce tools that allow for a comparison of user-defined datasets.

One aspect that is beyond the scope of this article is the automated identification of binding sites. It represents an important pre-processing step, for example, for the binding site annotation of novel targets. Cavity prediction is possible via elaborate binding site detection algorithms such as energy-based (SiteHound (Gherzi and Sanchez, 2009)), knowledge-based (ConCavity (Capra *et al.*, 2009)), and geometry-based (LIGSITE^{CS} (Huang and Schroeder, 2006)) methods. An overview over binding site identification software and its impact can be found elsewhere (Krone *et al.*, 2016).

In the following, we will first discuss different approaches to model small molecule binding sites with a special focus on one method per modeling approach (SMAP, FLAP, APF, SiteEngine). Second, the different model principles of those tools are explained in more detail. Afterward, we provide one application example per tool to illustrate the broad applicability of the software introduced herein. Finally, some hints are provided for successfully using binding site comparison tools.

Binding Site Modeling

The characterization of the binding site is a crucial part of the comparison process as it determines the final outcome of the study (Henrich *et al.*, 2010). The different binding site representation schemes are illustrated in Fig. 1. While some tools solely rely on residues and a crude abstraction of residue properties, other tools use more or less elaborate surface calculations for a projection of physicochemical properties on the binding site surface patches or solvent accessible residue atoms. Moreover, a continuous representation of pharmacophoric properties in 3D space can be applied, i.e., different pharmacophoric potentials are assigned to all 3D points. The probably highest level of abstraction is a comparison based on a description of the interactions between protein and ligand. The outcome of such methods is often highly dependent on the chemical nature of the small molecule interacting with cavity residues. In the following, one method per modeling scheme is explained in more detail to characterize the different concepts. For the remaining methods, a short summary is given.

Binding Site Modeling Based on Residues

A straightforward approach is the description of a binding site by 3D and physicochemical characteristics of the underlying residues. Nevertheless, a broad variety of modeling approaches is possible.

Table 1 Binding site comparison tools presented and discussed in this article

Software tool	Binding site representation	Model principle	Field of successful application (Ehrt <i>et al.</i> , 2016)	Availability
Cavbase (Schmitt <i>et al.</i> , 2001, 2002)	Residue-based	Graph	Protein–ligand interactions Virtual screening Evolutionary relationships Drug repurposing	CCDC
SMAP (Xie <i>et al.</i> , 2009)		Graph	Polypharmacology	Download
FuzCav (Weill and Rognan, 2010)		Fingerprint	Drug repurposing	Upon request
SiteAlign (Schalon <i>et al.</i> , 2008)		Fingerprint	Protein–ligand interactions	Upon request
PocketMatch (Yeturu and Chandra, 2008)		Distance lists	Protein–ligand interactions	Download
TM-align (Zhang and Skolnick, 2005)		Matrix	Function prediction Polypharmacology Homolog analysis Drug repurposing	Download
IsoMIF (Chartier and Najmanovich, 2015)	Interaction-based	Graph(grid)	Drug repurposing	Download
FLAP (Baroni <i>et al.</i> , 2007)		Fingerprint	Prediction of compound selectivity profiles and affinities	Molecular Discovery
KRIPO (Ritschel <i>et al.</i> , 2014)		Fingerprint	Off-target prediction	Download
TIFF (Desaphy <i>et al.</i> , 2013)		Fingerprint	Virtual screening	Upon request
APF (Totrov, 2011)	Observer point-based	3D-points (grid)	Off-target prediction Homolog analysis	Molsoft
ProBIS (Konc and Janezic, 2010)	Surface-based	Graph	Function prediction	Download
PSIM (Spitzer <i>et al.</i> , 2011)		3D-points (grid)	Off-target prediction	BioPharmics LLC
Shaper (Desaphy <i>et al.</i> , 2012)		3D points (grid)	Protein–ligand interactions	Upon request
SiteEngine (Shulman-Peleg <i>et al.</i> , 2004)		3D points	Protein–protein interactions	Download

Fig. 1 Four different ways of binding site modeling that are applied by the comparison algorithms presented in this article. The chosen example shows the binding site of coagulation factor Xa (1f0r.A@pdb) in complex with the nanomolar inhibitor RPR208815 in four different representation schemes.

The representation in SMAP (Xie *et al.*, 2009) relies on the residues' C α atoms as well as their characteristics. It is an extension of the previously developed algorithm named Sequence Order Independent Profile-Profile Alignments (SOIPPA) (Xie and Bourne, 2008). Binding sites are represented by C α atoms and a mesh surface based on their Delaunay tessellation. Each C α atom is assigned a normal vector that is perpendicular to the surrounding surface and a weight that accounts for chemical similarity and evolutionary relationship. The McLachlan (1971) chemical similarity matrix is utilized to represent physicochemical similarity. It is based on polar or non-polar character, size, shape, and charge of residues. A position-specific scoring matrix of the 20 amino acids which depends on the residue's sequence position expresses the evolutionary relationship. Taken together, the binding site C α atoms, their spatial orientation, and the weights of their respective residues are modeled by a graph.

The basic idea of Cavbase (Schmitt *et al.*, 2001, 2002) is to characterize the binding site properties by means of pseudocenters representing the physicochemical properties of binding site residue moieties: hydrogen bond acceptor and donor, mixed hydrogen bond acceptor/donor, center of an aromatic ring, centers comprising π electrons, aliphatic groups, and metal ions. In FuzCav (Weill and Rognan, 2010), the C α atom coordinates of binding sites are labeled with six pharmacophoric properties of the respective residue: hydrogen bond acceptor and donor, positive and negative ionizable, aromatic, and aliphatic. A final fingerprint representation encodes all unique pharmacophore triplets and the respective binned C α atom distances. PocketMatch (Yeturu and Chandra, 2008) classifies binding site residues according to their physicochemical properties: aliphatic, positively and negatively polarized, aromatic, and polar. They are represented by three types of points (C α , C β , the geometric center of the side chain atoms). SiteAlign (Schalon *et al.*, 2008) includes topological properties (e.g., side chain orientation, size) as well as physicochemical properties (e.g., hydrogen bond acceptor/donor, charge, aromaticity). These characteristics are projected on a discretized 80 triangle sphere by deriving a geometrical vector from the C α atom of each binding site residue to the sphere center. The TM-align (Zhang and Skolnick, 2005) algorithm was originally developed for protein structure alignment. Nonetheless, it was also successfully applied to compare protein binding sites. The comparison is based on the C α coordinates and the underlying secondary structures elements based on the DSSP assignment (Kabsch and Sander, 1983). However, TM-align is the only approach presented herein which is sequence order dependent, i.e., a discontinuous alignment of binding site residues is impossible.

Binding Site Modeling Based on Interactions

These methods represent the binding site by modeling known ligand interaction patterns to find distinct relationships between pockets. However, some of them rely on the presence of structurally characterized protein-ligand complexes and are not suited to compare novel predicted binding sites against already known ones.

Fingerprints for Ligands and Proteins (FLAP) (Baroni *et al.*, 2007) utilizes GRID (Goodford, 1985) molecular interaction fields (MIFs) to analyze the protein cavity. Six probes (probes for hydrogen bond interactions, salt bridges, hydrophobic interactions, shape etc.) can be chosen to define energetically favorable and unfavorable interactions for the binding site of interest. This

information is used to determine target-based pharmacophoric points using a weighted energy-based function. All possible energetically favorable arrangements of four pharmacophoric points are generated. A subsequent selection of groups of most important points can be achieved manually or automatically. Finally, a fingerprint is derived based on the distances, probe types, and chirality as four probes assume relative chiral positions in 3D space.

MIFs are also the basis for the method IsoMIF (Chartier and Najmanovich, 2015), but the GetCleft (Gaudreault *et al.*, 2015) algorithm is used to label grid points with the interaction energy for different probes. The final MIF is the set of interaction vectors at all vertex positions in the grid. Key Representation of Interaction in Pockets (KRIPO) (Ritschel *et al.*, 2014) uses intermolecular interaction features and generates 3-point pharmacophore fingerprints for ligands as well as for ligand fragments. Each triplet is encoded by the interaction properties and binned distances. Pharmacophoric properties including cation-aromatic interactions and metal coordination are also used for Interaction Fingerprint Triplets (TIFF) (Desaphy *et al.*, 2013). The interaction patterns can be represented by the protein atom coordinates, the ligand atom coordinates, or those of the geometric center of two interacting atoms.

Binding Site Modeling Based on Continuous Binding Site Properties

The method Atomic Property Fields (APF) (Totrov, 2011) treads another and unique path for modeling. It relies on a continuous binding site representation using seven atom properties: hydrogen bond acceptor and donor, lipophilicity, size, electronegativity, charge, aromaticity/hybridization. They are projected on a grid by the means of Gaussian functions. The binding site comprises all receptor atoms within a 6 Å radius of the bound ligand. The method is derived from an approach to describe the similarity of 3D property distributions of two ligands, which led to an optimized measure of chemical similarity (Totrov, 2008).

Binding Site Modeling Based on Surface Properties

The assignment of physicochemical properties in SiteEngine (Shulman-Peleg *et al.*, 2004) is similar to that of the Cavbase (Schmitt *et al.*, 2001, 2002) approach. The atoms of each binding site residue in a 4 Å radius of the binding partner are grouped according to their potential ligand interaction. A Connolly surface of the binding site is constructed and only pseudocenters with at least one surface exposed atom are retained. Pseudocenter triplets are generated and encoded with the respective side lengths and a physicochemical index.

Protein Binding Site (ProBiS) (Konc and Janezic, 2010) defines pseudocenters as realized in the Cavbase approach (Schmitt *et al.*, 2001, 2002). Solvent accessible surface atoms of a ligand binding site or a protein structure of interest are identified and labeled. Structurally related cavities can be identified based on binding sites or protein structures. In Protein SIMilarity (PSIM) (Spitzer *et al.*, 2011) the cavity is represented by surface moieties that can recognize a ligand. Distances to the molecular surface from so-called *observer points* are compared by placing them on a uniform grid. An additional weight is assigned in dependence of the minimum distance to the surface resulting in a defined number of *observer points*. Gaussian functions of the distance deviations from each *observer point* are calculated (minimum distance to any surface point to represent the shape, to a positive polarized atomic surface, and to a negative polarized atomic surface point). The binding site representation for Shaper comparisons is generated by VolSite (Desaphy *et al.*, 2012). A cube is placed at the center of mass of the bound ligand and filled with a grid. *IN* and *OUT* properties are assigned to the grid cells depending on the presence or absence of protein atoms and their degree of buriedness. The resulting site points are assigned pharmacophoric properties and a druggability prediction is performed. Drug-gable annotated binding sites can subsequently be compared.

Model Principles, Their Definitions, and Criteria for Similarity

The choice of an appropriate model principle is crucial for every application, so it is for the comparison of protein binding sites. The model principle defines and limits the level of abstraction, which is sometimes referred to as accuracy. It also defines the complexity of answering certain questions such as: what is the highest similarity of two given models? The complexity has a strong influence on the runtime required to answer such questions. There are three frequently used model principles: graphs, fingerprints, and points in 3D space. Fingerprints and graphs are classical data structures whereas points in 3D space are usually regarded as input data and the way they are stored and managed is referred to as their data structure (e.g., k-d trees (Bentley, 1975)). In contrast to these model principles, hashing is a function to map the input onto the output, without being a data structure such as graphs or fingerprints, and without an implicit similarity such as the root mean square deviation (RMSD) of points in 3D space.

Graphs

A graph $G=(V, E)$ consists of a set of vertices V and a set of edges E connecting these vertices. Metaphorically speaking, graphs contain objects and their relations to each other. In many of the available methods, both (vertices and edges) are labeled with additional information such as pharmacophore features at vertices and distances at edges for instance. The definition of the similarity of two given graphs is frequently based on the maximum common (induced) subgraph (MCS). A graph $G'=(V', E')$ is a

subgraph of $G=(V, E)$ if $V' \subseteq V$ and $E' \subseteq E$. It is said to be (vertex-)induced by V' if $E'=(V' \times V') \cap E$ holds. Let $G=(V, E)$, $G_1=(V_1, E_1)$, and $G_2=(V_2, E_2)$ be graphs. G is subgraph-isomorphic to a graph G_1 if there exists an injection $(\varphi): V \rightarrow V_1$ in such a way that $\forall u, v \in V: (u, v) \in E \Rightarrow ((\varphi)(u), (\varphi)(v)) \in E_1$. G is said to be a common subgraph of G_1 and G_2 if G is subgraph-isomorphic to G_1 and G_2 . The MCS G_{max} of G_1 and G_2 is a common subgraph of G_1 and G_2 for which $|G'| \leq |G_{max}|$ holds for all common subgraphs G' of G_1 and G_2 . Note that the MCS is not necessarily unique.

The determination of the MCS of two graphs can be reduced to the problem of finding the largest clique in an appropriately defined modular product graph, also known as compatibility, correspondence, or association graph and was first described by [Levi \(1973\)](#). A clique C in an undirected graph $G=(V, E)$ is a subset of vertices $C \subseteq V$ such that every two distinct vertices are adjacent. In a modular product graph $G_P=(V_P, E_P)$ of two labeled graphs $G_1=(V_1, E_1)$ and $G_2=(V_2, E_2)$ the set of vertices $V_P \subseteq V_1 \times V_2$ contains a vertex (v_1, v_2) with $v_1 \in V_1$ and $v_2 \in V_2$ if their labels are compatible. The set of edges E_P contains an edge connecting the vertices $(u_1, u_2), (v_1, v_2) \in V_P$ if either $e_1=(u_1, v_1) \in E_1$ and $e_2=(u_2, v_2) \in E_2$ and if their labels are compatible, or if $e_1 \notin E_1$ and $e_2 \notin E_2$. There is no general definition of the compatibility of labels.

The maximal clique detection algorithm by [Bron and Kerbosch \(1973\)](#) is widely used (e.g., by Cavbase, IsoMIF, ProBiS). It is a recursive backtracking algorithm that uses sets of vertices R (temporary result), P (possible extensions), X (excluded set) and finds the maximal cliques that include all of the vertices in R , some of the vertices in P , and none of the vertices in X . However, a graph $G=(V, E)$ can contain up to $3^{V/3}$ cliques ([Moon and Moser, 1965](#)) which makes their determination a demanding objective. Roughly speaking, a linear increase in the size of the input graphs may result in an exponential increase of cliques and therefore of the time required for their determination (runtime). There are optimizations available ([Tomita et al., 2006](#)) to reduce the branches of the recursion tree, the recursive calls, respectively.

SMAP represents ligand binding sites as graphs modeling C α atoms as vertices and the connections of the tessellation (mesh) as edges. The similarity of two graphs is based on determining the maximum weighted common subgraph (MWCS) which also uses an algorithm for the maximum-weight clique problem ([Kumlander, 2004](#)). This algorithm is based on the assumption that two vertices of an independent set cannot be in the same clique. An independent set is a set of vertices that are pairwise not connected by an edge (non-adjacent). The difference between a MCS and a MWCS is that the maximality is not based on the size of the subgraph but on the sum of weights reflecting the compatibility of each pair of matched vertices. Each such pair does not match in a binary manner (yes/no) but to a certain weight of compatibility. This weight is based on Gaussian density functions taking residue substitution matrices and geometrical properties into account.

Fingerprints

Fingerprints, such as molecular fingerprints ([Todeschini et al., 2009](#)) or extended-connectivity fingerprints ([Rogers and Hahn, 2010](#)), are widely used in bioinformatics, chemoinformatics, and computational biology. In general, fingerprints are vectorial descriptors consisting of binary or integer values. In the binary case, each value is usually correlated to the absence (0) or occurrence (1) of a certain property in the input. In the integer case, each value represents a counter for the number of occurrences of a certain property such as pharmacophore features or distances. The latter are usually binned to discrete value ranges. The major advantage of fingerprints is the ability to determine the similarity of two given fingerprints fast. Given two fingerprints $F_1=(v_1, v_2, \dots, v_n)$ and $F_2=(w_1, w_2, \dots, w_m)$ with $|F_1|=n$ and $|F_2|=m$ the similarity is defined by the number of compatible values at mapping indices. If both fingerprints are of equal length $n=m$, there is a direct mapping of v_1 on w_1 , v_2 on w_2 and so on. Otherwise, the fingerprints have to be aligned to obtain an indices mapping.

The definition of compatibility is trivial for binary values, but in the case of integer values, a slight deviation of values at mapping indices may still be defined as a match or compatible, respectively. A final score can be obtained using a similarity or distance metric such as the Tanimoto coefficient, which, among others, has proven to be a meaningful metric ([Bajusz et al., 2015](#)). It is based on the number of compatible values C , numbers of non-zero values Z_0 in F_1 and Z_1 in F_2 , and defined by: $Tanimoto(F_1, F_2)=C/(Z_0+Z_1-C)$. Thus, determining the similarity of two fingerprints is based on counting zero and non-zero values, which can be done by scanning both fingerprints simultaneously and once only. Thus, a linear increase in input size only results in a linear increase in runtime.

FLAP uses fingerprints in a different way. Here, a fingerprint representing a protein's binding site is an array of varying length containing several 11 integer value fingerprints. These 11 fields contain the information of one favorable arrangement of four pharmacophoric points, all pairwise distances of these points, and a value proportional to the sum of their energy. During the comparison of two protein binding sites P_1 and P_2 a fingerprint in P_1 similar to a fingerprint in P_2 is searched for. This is done by sorting the fingerprints with respect to their distances which supports the use of sophisticated search algorithms. Once a similar pair of fingerprints is found, the matching of the four pharmacophoric points of each fingerprint is used to determine the orientation of the corresponding binding sites. If these also superimpose within a certain threshold, the two protein binding sites are finally reported as similar.

Points in 3D

The comparison of clouds of points in 3D space $C_1=(p_1, p_2, \dots, p_n)$ and $C_2=(q_1, q_2, \dots, q_n)$ of the same size is in general an optimization problem of finding an alignment which has the lowest RMSD value: $RMSD(C_1, C_2)=\sqrt{\left(\frac{1}{n} \sum_{i=1}^n d(p_i, q_i)^2\right)}$ with

distance function d . During the optimization routine one cloud is usually fixed in space while the other one undergoes several translations and rotations to obtain an alignment with a minimum RMSD value. If the clouds are of different size, one has to define a mapping of the points of the smaller cloud onto the ones of the larger cloud.

APF utilizes a Monte Carlo algorithm to obtain a mapping of the two binding sites to be compared. A Monte Carlo algorithm is a randomized algorithm whose output may be incorrect with a certain probability. In contrast, a deterministic algorithm is always expected to give correct answers. APF uses a pseudo-Brownian Monte Carlo algorithm to minimize local gradients. In each iteration, the algorithm calculates a random rotation of the molecule with respect to chemical meaningfulness, for example, avoid atom clashes, to find a favorable and energetically minimized orientation. Although the selection of a randomized rotation is fast, several rotations are obtained and evaluated to find a satisfactory solution which is not necessarily the optimal one.

Hashing

Hashing has a broad field of applications among which are data storage, searching, and cryptography for instance. Hashing or more precisely a hash function f maps elements of a universe U to a set of keys K : $f: U \rightarrow K$. The basic idea is that $|U|$ is usually much larger than $|K|$ or even unlimited whereas K is of fixed size. Because of this, collisions can appear: $f(u) = f(v)$ with $u, v \in U$ and $u \neq v$. Therefore, the choice of a specific hash function for the universe of the individual application is crucial and should minimize the chance of collisions. A very simple hash function is the modulo function: $f(u) := u \bmod |K|$. However, there are many different hash functions such as double hashing using two hash functions, middle-square hashing based on [von Neumann \(1951\)](#), and Cuckoo hashing ([Pagh and Rodler, 2004](#)). A combination of a hash function and a fingerprint-like bit vector is the Bloom filter ([Bloom, 1970](#)). It is used to test whether an element $u \in U$ is a member of a set or not. If u is added to the set the bit at the index of the fingerprint obtained from the hash function applied on u is set to 1. In a test the algorithm also uses the function on u and checks whether the corresponding bit is set to 1 and if true, the element may be in. Otherwise, it is definitely not part of the set. Usually, a Bloom filter uses multiple hash functions.

Hashing is a comparably fast technique, but the runtime strongly relies on the complexity of the function itself, in particular the underlying input (e.g., graphs, fingerprints, integers, etc.).

The hash function of SiteEngine ([Shulman-Peleg et al., 2004](#)) is based on 4-tuples consisting of the side length of triangles defined by a triplet of pseudocenters and a physicochemical index encoding the properties of the pseudocenters. It is a geometric hash function and finds almost congruent matching triangles of which each pair defines a candidate transformation. The resulting matchings are finally re-evaluated by an elaborate filtering and scoring workflow to obtain the final superposition.

Examples for Successfully Applied Binding Site Comparison Tools

The following examples will illustrate that binding site similarities are by no means easily detectable via sequence or protein structure comparison. An abstraction of the various available binding site properties is often required. This abstraction and spatial comparison led to some astonishing results in the past. Examples for unrelated proteins with respect to sequence and overall fold that share similar ligands and highly similar binding sites underline the necessity of binding site comparison. Additionally, examples for similar proteins with rather dissimilar binding sites are given that underline the importance of binding site comparison to elucidate probable off-targets and ways to enhance selectivity. The examples were chosen to illustrate that various approaches that make use of different types of binding site modeling, comparison, and similarity scoring can shed light on highly interesting relationships between otherwise unrelated proteins.

Polypharmacology

The first example illustrates the impact of binding site comparison on polypharmacology ([Xie et al., 2011](#)). The binding site comparison tool SMAP ([Xie et al., 2009](#)) was used to compare the nelfinavir binding site of the HIV protease dimer (1ohr@pdb) against 5985 human protein structures or their homologues from other organisms. The 126 most similar superimposed protein binding sites were used for molecular docking of nelfinavir. This led to 92 putative off-targets. Most of the hits were protein kinases belonging to tyrosine, cAMP-dependent, cGMP-dependent kinase families, or protein kinase C family. Exhaustive MD (molecular dynamics) simulation studies and Molecular Mechanics/Generalized Born Surface Area (MM/GBSA) free energy calculations led to the conclusion that nelfinavir interacts with EGFR, might also interact with IGF-1R, FAK, Akt2, CDK2, ARK, PKD1, and will probably not bind to FGFR, EphB4 and Abl. In a subsequent biochemical screening, the authors provided evidence for a nelfinavir-induced inhibition of EGFR and ErbB2. **Fig. 2** shows a superposition of the protease (1ohr.A@pdb) and the EGFR pocket (2j6m.A@pdb) to illustrate the similarities.

Selectivity Profiling

The second example provides a glimpse into the wide variety of possible application domains for binding site comparison. The method FLAP was applied to correlate inhibition profiles for kinase inhibitors with identified binding site features for various kinase binding sites ([Sciabola et al., 2010](#)). Based on a binding site feature similarity matrix of fourteen protein kinases partial least-squares models were created to predict pIC₅₀ values. The authors of this study were able to choose a combination of probes

Fig. 2 Binding site similarities between the HIV protease (1ohr@pdb, green) and EGFR (2j6m.A@pdb, orange) based on a SMAP (Xie *et al.*, 2009) comparison. (A) Complete structures superimposed based on the binding site similarities. (B) A detailed view of the binding site similarities. Nelfinavir bound to HIV protease is shown in green sticks while the EGFR ligand with the PDB-ID AEE is represented by orange sticks.

Fig. 3 Comparison between homologous proteins from different Mycobacteria species and a human related enzyme. The MeaB structures from *M. tuberculosis* (3md0@pdb), *M. smegmatis* (3nxs@pdb), and *M. thermoresistibile* (3tk1@pdb) are represented in green, orange, and purple, respectively. The structure of the human homolog MMAA is shown in pink. Reprinted and modified with permission from (Ehrt *et al.*, 2016). Copyright 2016 American Chemical Society. (A) The superposition of all structures illustrates their close relationship. (B) A detailed comparison of the underlying binding sites provided insights into possible starting points to increase the selectivity of inhibitors towards the mycobacterial enzymes.

to generate MIFs that enabled them to predict the level of inhibition of a compound on different protein kinases. Consequently, this study underlines the possible impact of binding site comparison for selectivity prediction for protein kinase inhibitors.

Off-Target Analysis

The method APF was applied to analyze differences between the binding sites of homologous structures (Edwards *et al.*, 2015). The methylmalonyl CoA mutase-associated GTPase MeaB which is an essential enzyme for the growth of pathogenic bacteria (e.g., *Mycobacterium tuberculosis*) represents an interesting drug target. The nucleotide binding sites of crystal structures from different bacteria and a structure of the human homologous protein methylmalonic aciduria associated protein A (MMAA, 2www@pdb) were compared to analyze differences between the structures. They can be exploited to circumvent a possible inhibition of the human enzyme which might result in fatal methylmalonic aciduria. Fig. 3 shows the result of a binding site comparison between

Fig. 4 Binding site similarities between the Ubiquitin-conjugating enzyme E2 K (3k9p.A@pdb) and a surface patch of the ALIX-V domain (2ojq@pdb). The template structures of the Ubiquitin-conjugation enzyme E2 K is shown in green with the bound Ubiquitin molecule in purple. The ALIX-V domain is depicted in orange. (A) Superposition of both protein structures with respect to the identified local similarity. (B) Zoomed view to illustrate identified binding site similarities with respect to the ubiquitin binding site of the Ubiquitin-conjugating enzyme. Some of the crucial similarities between both binding sites are depicted and the involved residues are labeled accordingly.

three mycobacterial MeaB structures and the human MMAA. A proper visualization of the major dissimilarities can assist the development of safe MeaB inhibitors.

Protein–Protein Interactions

The last example illustrates the applicability of binding site comparison for the analysis of protein–protein interactions. SiteEngine (Shulman-Peleg *et al.*, 2004) which is based on similarities between surface patches of binding sites was utilized to analyze potential protein–protein interactions (Keren-Kaplan *et al.*, 2013). A template ubiquitin-binding domain represented the starting point to search for new potential ubiquitin-binding domains within the PDB. Ubiquitylation plays a crucial role in trafficking, for example, of retroviral transmembrane proteins. The ALIX-V domain (2ojq@pdb) was identified as new potential ubiquitin binding domain due to its high local similarity to the ubiquitin binding site. Subsequent protein–protein docking and experimental binding affinity measurements confirmed this result. The finding was also verified in an independent study (Dowlatshahi *et al.*, 2012). The match between the template structure (3k9p@pdb) and ALIX-V is depicted in Fig. 4.

Remarks Concerning Binding Site Comparison

Finally, we want to provide some useful hints which might assist in applying binding site comparison tools and software for various projects.

First, proteins are no rigid constructs as commonly observed in protein crystal structures. NMR structures and MD simulations can provide useful information with respect to flexible protein regions and binding site flexibility. The knowledge of binding site dynamics can have a huge impact on computational strategies (Stank *et al.*, 2016). As shown in previous studies, it can be beneficial to use an ensemble of binding site structures to identify or compare ligand binding sites (Lanig *et al.*, 2015; Miguel *et al.*, 2015; Möller-Acuña *et al.*, 2015; Zhao *et al.*, 2012). This is especially important as the results of some comparison algorithms are very sensitive toward binding site definition. Given a large amount of crystal structures of the protein bound to different ligands, all available binding sites should be considered.

Moreover, although various methods provide some measure of significance to analyze the impact of the identified similarities, the obtained results should be visualized and rationalized. Sometimes the use of two or three tools is advisable. Different binding site comparison methods were evaluated by the means of highly distinct datasets and designed to address problems of varying application domains. Therefore, the used benchmark datasets can provide insights to appropriate tools for the aim of the study. Tools validated with respect to classification performance are promising tools to infer evolutionary relationships and protein function. Other tools were analyzed using datasets of proteins binding similar ligands. Those might be an appropriate choice for applications such as off-target prediction, polypharmacology, and drug repurposing. Nevertheless, there are examples for various tools that underline their impact on fields they were not developed for.

A further challenge is the ranking of binding site similarities. Many tools offer different similarity measures and it is often beneficial to use a scoring scheme that is most appropriate for the aim of the study. A method which models and compares a binding site based on residues might nonetheless offer scores that consider the shape overlap of two cavities or common interaction patterns. This issue was not addressed in this article and the reader is referred to the publications cited herein.

Finally, a database search cannot only be performed based on known binding sites. In cases of novel targets, it is highly recommended to predict binding sites based on geometrical, evolutionary information, or probe interaction potentials and compare them against large databases of annotated binding sites (e.g., sc-PDB (Kellenberger *et al.*, 2006)) to gain insights into potential druggable binding sites.

Biographical Sketch

Christiane Ehrt received her MSc in Biochemistry at the Martin-Luther-University Halle-Wittenberg. Currently, she works as a PhD student at the Faculty of Chemistry and Chemical Biology at the TU Dortmund University in the group of Dr. Oliver Koch. Her interests and current focus include the identification and comparison of protein ligand binding sites, virtual screening studies for novel targets, and in this context, comparative modeling, MD simulations, and biochemical assay development. Tobias Brinkjost received his Diploma in Computer Science from the TU Dortmund University in 2012. Afterward he joined the Medicinal Chemistry group of Dr. Oliver Koch in collaboration with the Chair for Algorithm Engineering of Prof. Dr. Petra Mutzel at the TU Dortmund University for his PhD studies. His current research mainly focusses on the development of models and algorithms in the field of rational drug design. Oliver Koch studied pharmacy and computer science at the Philipps-University Marburg, Germany, where he also obtained his PhD in Pharmaceutical Chemistry with Prof. G. Klebe. After postdoctoral research at the Cambridge Crystallographic Data Center in 2008 and working in drug discovery at MSD Animal Health Innovation, he started his independent academic career in 2012 as an independent junior group leader for medicinal chemistry at the TU Dortmund University, Germany. His research interests involve the development and application of computational methods in computational molecular design and medicinal chemistry.

Quantitative Structure-Activity Relationship (QSAR): Modeling Approaches to Biological Applications

Introduction

Quantitative structure-activity relationship (QSAR) approach relies on the basic principle of chemistry that states that the biological activity of any ligand or compound is associated with the arrangement of atoms forming the molecular structure. In other words, structurally related molecules possess similar biological activities. This structural information can be defined in terms of a series of parameters called molecular descriptors. In QSAR, the biological activity is represented as a function of these molecular descriptors as depicted in Eq. (1).

$$\text{Biological response or activity} = f(\text{molecular descriptors}) \dots \quad (1)$$

The model thus developed based on the biological activities of known ligands is used to predict the response of new compounds.

QSAR finds applicability in a wide range of fields including toxicology (Wang *et al.*, 2014; Rochani *et al.*, 2010), ecotoxicology (Hermens *et al.*, 1984; Van Gestel and Ma, 1990; Escher *et al.*, 2006), drug design and discovery (Zernov *et al.*, 2003; Speck-Planche *et al.*, 2012; Buolamwini and Assefa, 2002), chemical data mining (Shen *et al.*, 2004), combinatorial library design (Ghose *et al.*, 1999; Zhang *et al.*, 2008) and so on.

QSAR studies therefore involve selection of active and inactive compounds with the measure of their biological activity, description and calculation of molecular descriptors, selection of appropriate features followed by construction of the mathematical model and its evaluation.

QSAR and QSPR

Quantitative structure-activity relationship (QSAR) prediction depends on the structure of molecules and atoms present in the compound. Biological activity is understood in terms of numerical values (example bioavailability, inhibitory concentration) and presence/absence of a condition (example infected/not infected, mutagenic/non mutagenic). Various QSAR studies have been carried out to understand biological properties such as pharmacokinetics (Vieira *et al.*, 2014; Gombar and Hall, 2013), blood brain barrier penetration (BBB) (Zhang *et al.*, 2008), carcinogenicity (Fjodorova *et al.*, 2010; Kar and Roy, 2011), drug metabolism (Braga and Andrade, 2012; Lewis, 2000), bio-concentration (Grisoni *et al.*, 2016; Papa *et al.*, 2007), permeability (Gozalbes *et al.*, 2011; Fujikawa *et al.*, 2007), drug clearance (Manga *et al.*, 2003; Boik and Newman, 2008), mutagenicity (Valencia *et al.*, 2013; Barber *et al.*, 2016), and so on. Another term associated with this approach is Quantitative structure-property relationship (QSPR). In QSPR, physiochemical properties of the chemical compounds are determined based on the molecular structure information. Physiochemical properties such as melting point (Katritzky *et al.*, 2002; Modarresi *et al.*, 2006), boiling point (Sola *et al.*, 2008; Dai *et al.*, 2013), solubility (Duchowicz and Castro, 2009; Gao *et al.*, 2002), stability (Dioury *et al.*, 2014; Ghasemi *et al.*, 2010), dielectric constant (Achary, 2014; Soltanpour *et al.*, 2016), reactivity (Toropov *et al.*, 2004), diffusion coefficient (Mirkhani *et al.*, 2012), thermodynamic properties (Puri *et al.*, 2002; Duchowicz *et al.*, 2006), hydrophobicity (Zou *et al.*, 2016; Berinde, 2013) have been exploited to determine quantitative structure-property relationships.

History

The concept of QSAR had begun a century ago. Crum-Brown and Fraser in 1868 proposed the physiological activity of molecules based on their composition (Crum-Brown and Fraser, 1868). Then the narcotic effect of the primary alcohols respective to the molecular weight was studied by Richardson in 1869 (Richardson, 1869). Following this, studies of simple organic compounds in response to water solubility (Richet, 1893), potency variation of narcotic compounds (Meyer, 1899), study of chemical reactivity of substituted benzenes (Hammett, 1937), narcotic study based on logP and thermodynamic (Ferguson, 1939), physical organic chemistry to linear steric energy relationships (Taft, 1952, 1953a, 1953b), linear free energy relationship model by Hansch and Fujita (1964), QSAR study based on molecular fragments by Free and Wilson (1964) and substituent-based structure-activity

¹Equal contribution.

relationship (Fujrra and Ban, 1971) are some of the important hallmarks in the history of QSAR. The development of 2D-QSAR began in early 1970s and the development of 3D-QSAR started in early 1980s. With the arrival of new technologies and perspectives, QSAR has now become multidimensional. More robust and accurate QSAR approaches came into practice with increased dimensionality like 4D, 5D and 6D, which has led to increased predictability, reliability and precision of the models.

Types of QSAR Methodologies

QSAR can be broadly classified in two ways (Qiao *et al.*, 2014). The first classification is based on the dimensions of the descriptors involved in the model such as 1D, 2D, 3D, 4D, 5D and so forth. Other is based on the type of biological activity predicted as a dependent variable. This includes Quantitative structure-toxicity relationship (QSTR) (Can, 2014), Quantitative structure-metabolism relationship (QSMR), Quantitative structure-reactivity relationship or Quantitative structure-retention relationship (QSRR) (Hemmateenejad *et al.*, 2009; Goryński *et al.*, 2013), Quantitative structure-permeability relationship or Quantitative structure-pharmacokinetics relationship (QSPR) (Moss *et al.*, 2002; Mayer and Van De Waterbeemd, 1985), Quantitative structure-bioavailability relationship or Quantitative structure-binding affinity relationship (QSBR) (Andrews *et al.*, 2000; Zhang *et al.*, 2006), and so forth.

QSAR models can also be grouped based on analysis of correlation-linear and non-linear (Roy and Mandal, 2008), or depending on binding nature of molecule and receptor-receptor dependent and receptor independent (Magdziarz *et al.*, 2009).

QSAR Model Construction

The quality of the QSAR model to a large extent depends on the data used for its construction. Hence, prior to the model development, it is necessary to gain insights about the data. Thorough understanding of the problem and influencing factors assists in discerning meaningful relationships. Relevant background information about the system under study either biological or chemical is to be collected via literature search. Data sets for model construction need to be chosen carefully as poor and inconsistent data would lead to corrupt model. There are several other factors like division of data into training and test data sets, molecular descriptors, statistical methods for model development that influence the quality of the QSAR model.

The schematic representation of QSAR model construction is given in Fig. 1. A brief description of the steps involved in QSAR model generation is discussed in the following section.

Fig. 1 Schematic representation of QSAR (quantitative structure-activity relationship) model development.

Data Pre-Processing

Pre-processing eliminates noise and redundancy in the data sets. It involves data transformation that includes smoothing, normalization and aggregation (Tomar and Agarwal, 2014), data reduction, sampling when data sets are large, noise elimination, feature selection, data cleaning, data integration when data is collected from heterogeneous sources, and discretization (Cocu *et al.*, 2008).

Training and Test Data Sets

The data is divided into training and test data sets. The training set is used to formulate the QSAR model, while the test set is used to evaluate its predictability and accuracy. Dataset is generally divided in such a way that both the sets occupy entire descriptor space. Employing appropriate data splitting techniques improves the model prediction. The various approaches available for the division of dataset include k-means clustering, based on X response, based on Y response, random selection, statistical molecular design, sphere exclusion, Kennard-Stone selection, Kohonen's self-organizing map selection, and extrapolation-oriented test set selection (Roy *et al.*, 2008).

Calculation of Molecular Descriptors

The information about the structure of molecules, defined by molecular descriptors obtained from different representations such as 2D, 3D, etc., is embedded into the QSAR model. Molecular conformations used should be correct for a better predictive model. There are different kinds of descriptors like count descriptors (0D), fingerprints (1D), topological descriptors (2D), geometrical (3D), grid based (4D) and so forth. The complexity of information and power to discriminate between similar structures as provided by different descriptors increases with dimensionality. 0D and 1D descriptors provide basic information like molecular weight and number of constituent elements that are directly derived from molecular formula. Net charge of the molecule is a 1D descriptor. Topological indices that are computed from the structural formula are 2D descriptors. These are based on the graph theory and reflect the connections in the structure. The most widely used topological descriptor is connectivity index proposed by Randić (2001); Li and Shi (2008); Kier (1985). Other topological indices are Wiener's index W (Ivanciuc, 2000; Wiener, 1947), Connectivity indices (Kier *et al.*, 1975), Kier Shape (Kier, 1985), Balaban J Index (Balaban, 1982) and Zagreb indices (Gutman and Trinajstić, 1972). The 3D descriptors are based on three-dimensional coordinates of atoms comprising the compounds. Some commonly used methods for calculating 3D descriptors are CoMFA, CoMSIA, CoMBINE, GERM, CoMMA, GRIND, WHIM, HoloQSAR and CoSA. 4D, 5D and 6D descriptors are multidimensional descriptors, which include the parameters involved in the structure and flexibility of the receptor-binding site in conjunction with ligand topology. 4D descriptors are based on reference grids and molecular dynamic simulations. Descriptors calculated using multiple conformations, orientations, protonation states and isosteromers of the ligand constitute 5D descriptors. The solvation terms constitute 6D descriptors. Molecular descriptors can be calculated using various software, some of which are listed in Table 1 (Damale *et al.*, 2014).

Feature Selection

Feature selection reduces the dataset horizontally. Among the large number of calculated descriptors, only few are chosen to define the model. Feature selection after descriptor calculation removes collinearity between the descriptor pairs. Selection of the most appropriate features is done using filter and wrapper methods (Goodarzi *et al.*, 2012). Filter methods involve filtering out descriptors, thereby reducing the pool size of descriptors based on inter-variable correlations. So, molecular descriptors that show inter-correlation are removed retaining only one descriptor from a pair (Roy *et al.*, 2015a). Descriptors with lowest variance are also removed. Filter methods use techniques like chi-square analysis, Shannon entropy, odds ratio, GSS coefficient (Liu, 2004), correlation based feature selection (Demel *et al.*, 2009), Fisher Score, Kolmogorov-Smirnov statistics (Guyon *et al.*, 2002), and principle component analysis. Distance based methods like Euclidean distance measures are also grouped under filter methods. Wrapper methods use regression-based approaches to select descriptors. In general, wrapper methods involve more computational power and perform better than filter methods. Recursive feature elimination (Xue *et al.*, 2004), variable selection and modeling based on the prediction (Liu *et al.*, 2003), k nearest neighbor, backward elimination, forward selection, genetic algorithm, Bayesian regularized neural network, factor analysis and combinatorial protocol are some of the commonly used wrapper methods. Hybrid methods are also being used that combine both filter and wrapper methods for selecting features (Goodarzi *et al.*, 2012).

Table 1 Software for calculation of molecular descriptors

Software	Description	Availability
ACD/LogP Freeware	logP prediction by fragment-based algorithm	Freely available
Dragon	Calculation of topological, constitutional & geometrical descriptors	Commercial
MOLGEN	Calculation of topological, constitutional & geometrical descriptors	Freely available
PaDEL Descriptors	Calculation of 2D & 3D descriptors	Freely available

Heuristic methods based on multiple linear regression are also used in selecting descriptors for QSAR models. It is fast when compared to other methods. It discards descriptors with constant values and removes descriptors whose values are not available for all the structures in the dataset thereby removing trivial descriptors. It also removes highly correlated descriptors (Liu and Long, 2009). Heuristic method has used for searching descriptor space and selection of vital descriptors in QSAR study of 1,4-dihydropyridine calcium channel antagonists (Si *et al.*, 2006), to select descriptors for multivariable linear model to predict the Percent of Applied Dose Dermally Absorbed (PADA) of the polycyclic aromatic hydrocarbons (Wang *et al.*, 2008), and descriptors selection in QSAR analysis of photosystem II electron transfer inhibitors (Karacan *et al.*, 2012).

QSAR Methods

Statistical methods are used in model construction and feature selection when there are large numbers of descriptors. They are helpful in obtaining functional endpoints. The statistical methods can be classified into regression-based approaches, classification based approaches, and machine learning techniques. QSAR modeling can be done for both linear and non-linear properties. Some of the methods for modeling linear properties include linear regression and partial regression, while artificial neural networks are being employed for modeling non-linear properties.

Models can be constructed using both supervised and unsupervised techniques. The chance effects in the unsupervised learning are less when compared to supervised learning, as it does not change to fit the model. Semi-supervised learning is advantageous over the supervised and unsupervised techniques. It considers both the labeled and unlabeled data giving better performance (Settles, 2012). Comparison of supervised learning algorithms and semi-supervised algorithms in different data sets suggested that semi-supervised learning can assist in understanding the addition of unlabeled data and hence is helpful for certain type of dataset and methods (Levatic *et al.*, 2013).

Regression based methods

Multiple linear regression

Multiple Linear Regression (MLR) method helps in establishing correlation between the independent and dependent variables. Here, the dependent variables are the biological activity or physiochemical property of the system that is being studied and the independent variables are molecular descriptors obtained from different representations. In linear regression models, the dependent variable is predicted using only one descriptor or feature. Multiple linear regression models consider more than one descriptor for the prediction of property/activity in question. The model based on the linear regression can be represented as a mathematical equation given below-

$$y = a + bx \dots \quad (2)$$

where, y is the dependent/response variable representing the physiochemical property or biological activity, x is the independent or predictor variable accounting for the molecular descriptor, and b is the regression coefficient.

Examples of QSAR studies involving the use of MLR method include the prediction of binding affinities of H3 antagonists (Dastmalchi *et al.*, 2012) and inhibitory activity of human non-pancreatic secretory phospholipase A₂ (Singh and Verma, 2014).

Partial least squares method

Partial Least Squares (PLS), developed from the principal component regression, helps in building models predicting more than one dependent variable (Lorber *et al.*, 1987). This method is used when the number of variables are more than the number of compounds in the datasets and where the variables considered for the study are correlated (Cramer, 1993). It is applied in 3D-QSAR technique, Comparative Molecular Field Analysis (CoMFA) to reduce the number of descriptors. PLS is also used in the validation metrics of the models (Mota *et al.*, 2009). It is advantageous over other regression models (Cramer, 1993). PLS has been used in the construction of many successful QSAR models. Prediction of binding affinity of polycyclic aromatic compounds with the rat liver 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD) receptor (Johnels *et al.*, 1989) is one such example. PLS in combination with other methods – Genetic Partial Least Squares (G/PLS), Factor analysis Partial Least Squares (FA-PLS) and Orthogonal Signal Correction Partial Least Squares (OSC-PLS) (Liu and Long, 2009) is also being used for QSAR studies.

Classification based methods

Cluster analysis

Clustering involves placing similar data into a group in a way that maximizes similarity within groups and dissimilarity between groups. It involves methods like hierarchical clustering and k-means clustering. In hierarchical clustering, clusters are grouped on the basis of the dissimilarities calculated through the distances between the objects (Euclidean distances). The k-means clustering is a non-hierarchical method. It is based on k-centroids. Some of the other classification based methods are linear discriminant analysis and logistic regression (Roy *et al.*, 2015c; Agresti, 2007; Harrell, 2001).

Machine learning techniques

Artificial neural network

Artificial Neural Network (ANN) mimics the behavior of biological neurons. The ANN has input layer, hidden layer(s) and output layer. The molecular information is fed through the input layer, which is processed by a number of processing units in

parallel and the biological activity or property is obtained as an output. The commonly used ANNs in QSAR are back propagation neural networks, probabilistic neural networks, Kohonen self-organizing maps and Bayesian regularized neural networks. Neural networks can be supervised or unsupervised in nature. The learning is supervised when the trained model is validated by a separate test set. The training set helps in fitting weight parameters and decides the number of hidden layers in the network architecture. ANN methods have been proven to be highly adaptable and are deployed in modeling non-linear systems with high variability in data sets. Superior models can be obtained from ANNs compared to traditional approaches like MLR and PLR (Shi *et al.*, 2010). Implementing techniques like dropout in training data set reduces over-fitting of data and produces improved results when compared to conventional ANN models. However, Bayesian networks still outstand in their performance.

ANNs have been recently used in many QSAR studies. Some examples include the study of neurotrophic effects of N-p-Tolyl/phenylsulfonyl L-amino acid thioester derivatives (Luo *et al.*, 2011) and the study of antibacterial activity of oxazolidinone derivatives (Zou and Zhou, 2007).

Support vector machine

Support Vector Machine (SVM) is a machine learning approach that uses a linear classifier to classify data into two categories. The classifier is non-probabilistic. It performs better than other 3D QSAR models. In a comparative study of 3D QSAR modeling and SVMs for predicting the activity of BRAF-V600E and HIV integrase inhibitors, SVMs outperformed 3D-QSAR models (Wesley *et al.*, 2016). SVMs are also being used in combination with other methods like MLR, PLS and so forth for building more powerful and accurate QSAR models. In one of the QSAR reports where the anti-Alzheimer activity of triazolythiopenes as cyclin dependent kinase 5 inhibitors was studied (Garkani-Nejad and Ghanbari, 2016), MLR was used for selecting molecular descriptors, and support vector regression and PLS were used for constructing non-linear and linear models. When these methods were compared, support vector regression outperformed other methods. SVMs are employed in dimensionality reduction through variable ranking and selection (Bi *et al.*, 2003). SVMs also overcome the issue of over-fitting observed in artificial networks.

In a study conducted for predicting the reduction of dihydrofolate reductase by pyrimidines, SVMs outperformed three neural networks, namely radial basis function network, nearest neighbor classifier and decision tree (Burbidge *et al.*, 2001). QSPR models are also being developed by employing a combination of SVM with other methods like Principal Component Least Square methods and so forth (Veyseh *et al.*, 2015; Khorshidi *et al.*, 2014).

Gene expression programming

Gene Expression Programming (GEP) is based on the genetic algorithm and genetic programming. GEP has been used in QSAR modeling for the prediction of dermal penetration (PADA, Percent of Applied Dose Dermally Absorbed) of polycyclic aromatic hydrocarbons (Wang *et al.*, 2008), prediction of EC₅₀ of anti-HIV drugs (Si *et al.*, 2008), prediction of binding affinity of substituted 1-(3,3-diphenylpropyl)-piperidiny l amides and ureas with the chemokine receptor 5, and also for the prediction of toxicity of aromatic compounds (Shi *et al.*, 2010). GEP proved to be better in prediction when compared to the previously discussed methods like ANNs (Shi *et al.*, 2010), and SVMs (Si *et al.*, 2008). Further, Improved Gene Expression Programming (IGEP) proves to be more efficient than existing methods (Fu *et al.*, 2010).

Some of other methods deployed in QSAR studies include Monte Carlo Simulations (Kumar and Chauhan, 2017), principal component analysis (Suzuki *et al.*, 2001), and decision trees and random forest algorithm (Polishchuk *et al.*, 2009; Simeon *et al.*, 2016). Still newer methods like Projection Pursuit Regression (Du *et al.*, 2011) and Local Lazy Regression (Guha *et al.*, 2006; Lei *et al.*, 2010) are also implemented in QSAR models.

Software for QSAR Studies and Modeling

QSAR studies are carried out using various platforms that help in building models for predicting chemical, biological and toxicological activities. Some of these are listed in Table 2.

List of Databases Used in QSAR Studies

Attempt has also been made to archive the constructed QSAR models for further reference and usage. Some of these are listed in Table 3.

Validation of Models

Once the model is constructed, it must be validated. Validating the models avoid chance correlation of numerous descriptors used in the model and also over-fitting of data. It helps in assessing the accuracy and prediction of the model. The Organization for Economic Cooperation and Development (OECD) has put forth five principles to test the model. They are (1) a defined endpoint,

Table 2 Platforms used for QSAR modeling

Software	Description	Availability
3D-QSAR	To build 3-D QSAR models	Freely available
ACD/Tox Suite	Used for prediction of toxicity endpoints	Commercial, free web service
ADMET Predictor	Calculation of ADMET properties	Commercial
AZOrange	Machine learning platform for QSAR modeling	Freely available
BioPPsy	Prediction of pharmacokinetic properties of drug candidates by QSPR modeling	Freely available
BioTriangle	Web-based platform for calculating molecular descriptors	Freely available
BlueDesc	Molecular Descriptor Calculator	Freely available
CACTVS	Molecular Descriptor Calculator	Freely available
CAESAR	Models for developmental toxicity	Freely available
ChemDes	Descriptor and fingerprint calculation (web-based)	Freely available
CODESSA	Generate predictive QSAR models from Quantum chemical, topological & electrostatic descriptors	Commercial
CoFFer	Web-based QSAR service for the prediction of chemical compounds	Freely available
CORALSEA	Building of quantitative structure - property / activity relationships	Freely available
Derek	Rules based system with structural alerts for developmental toxicity, teratogenicity, testicular toxicity, and oestrogenicity	Commercial
DMax	Data mining tool for QSAR, virtual screening and compound screening data analysis	Freely available
DWFS	Parallel GA wrapper Feature selection (web-based)	Freely available
ECOSAR	Calculates aquatic toxicities	Freely available
EPISuite	Suite of programs for estimation of physiochemical property calculation and environmental fate	Freely available
eTOXlab	Development and validation of QSAR models	Freely available
GUSAR	Development of QSAR/QSPR models (web-based)	Freely available
HASL	Software package for 3D-QSAR	Commercial
HYBOT-PLUS	Descriptor calculation	Commercial
Leadscope	QSAR models to predict reproductive and developmental toxicity for rodent foetus	Commercial
Mathematica	Software package for ANN development	Commercial
Matlab	Software package for ANN development	Commercial
MC – 3DQSAR	Generates QSAR equations	Freely available
Molcode Toolbox	Prediction of toxicological endpoints	Commercial
MultiCASE	Models for developmental toxicity	Commercial
Neuralware	Software package for ANN development	Commercial
OECD QSAR Application Toolbox	QSAR models to fill data gaps & missing data	Freely available
PASS	Predicts biological activity using Bayesian algorithm, predicts embryotoxicity and teratogenicity	Commercial
QSARpro	Predicts activity and optimizes lead compounds using QSAR models	Commercial
SPSS	Software package for ANN development	Commercial
Statistica	Software package for ANN development	Commercial
TerraQSAR	Database compounds with structure-specific Biological activity	Freely available
T.E.S.T	Predicts toxicities of compounds by applying QSAR methodologies	Freeware
TIMES	Prediction of oestrogen, androgen and aryl hydrocarbon binding compound	Commercial
TOPKAT	Prediction of toxicological endpoints	Commercial
Toxmatch	Provides chemical similarity indices to assist in read-cross assessments & developing categories	Freely available
WEBCDK	Calculation of molecular descriptors (web-based)	Freely available
VCCL	Suite of programs for descriptor calculation, dimensionality reduction & data analysis	Freely available
VEGA-QSAR	QSAR models for regulatory purposes can be accessed and new QSAR models can be built	Freely available
NVirtualToxLab	Based on the combination of Auto flexible docking and mQSAR	Commercial

(2) an unambiguous algorithm, (3) a defined domain of applicability, (4) appropriate measures of goodness-of-fit, robustness and prediction accuracy, and (5) a mechanistic interpretation, if possible (Roy *et al.*, 2015b). Models can be validated through techniques such as internal validation, external validation, and cross validation (Veerasamy *et al.*, 2011). In internal validation, activity is predicted and parameters are estimated to analyze the precision of the prediction based on the compounds used for model construction. This is not suitable when new test set of compounds is used. But the external validation technique works well

Table 3 List of databases related to QSAR studies

Database	Description	URL
Danish QSAR database	Database of QSAR predictions	http://qsar.food.dtu.dk
ECOTOX	Online database that provides toxicity data on aquatic life, terrestrial plants & wild life	https://cfpub.epa.gov/ecotox/
EDKB (Endocrine Disruptor Knowledge Base)	Online database with predictive models to predict binding affinity of the compounds with oestrogen & androgen nuclear receptor proteins	http://edkb.fda.gov/webstart/edkb/index.html
JRC QSAR Model Database	Database of QSAR models	https://eurl-ecvam.jrc.ec.europa.eu/databases/jrc-qsar-model-database
MOE	Database of molecular data and QSAR modeling	https://www.chemcomp.com/MOE-Molecular_Operating_Environment.htm
MOLE db	Free database for molecular descriptors	http://michem.disat.unimib.it/mole_db/
QsarDB	Database of QSAR/QSPR models	https://qsar.db.org/

even with the new datasets. In this case, the dataset is divided into test and training data sets. Model validation is done by test set compounds that are independent of training set (Roy *et al.*, 2015b; Veerasamy *et al.*, 2011; Roy and Kar, 2015). However, external validation is not worthy as it leaves a large portion of data set for testing (Hawkins *et al.*, 2003). Golbraikh and Tropsha (2002) proposed high value of cross-validated R^2 to be one of the criteria to have high predictive power for a QSAR model. It was emphasized that depending on q^2 for predictivity is incorrect. Instead external data set should be used for validation to have high predictive power for the model (Golbraikh and Tropsha, 2002).

Validation metrics are of two types based on type of QSAR model (Kar and Roy, 2011; Roy *et al.*, 2015b).

1. Regression-based QSAR models
2. Classification-based QSAR models

Both regression and classification based methods have their unique metrics for validation.

Validation Metrics for Regression-Based Methods

Validation metrics for regression-based models are calculated for both internal and external validation strategies.

Validation metrics for internal validation

Internal validation of QSAR models employs the use of molecules from training set to test the predictability of the model. Some of the most common methods used for internal validation of QSAR models are described here.

Least square fitting

Least square fitting is similar to linear regression and is the most commonly used validation method. It is the measure of square correlation coefficient (R^2) between the predicted and experimental value of activity. Outliers can be removed from the training data set, in order to optimize QSAR model, if difference between R^2 and R^2_{adj} is less than 0.3 (Veerasamy *et al.*, 2011).

Chi-squared (χ^2) and root-mean squared error (RMSE)

The χ^2 and RMSE values are used to assess the predictive quality of a model. χ^2 value shows the difference between experimentally determined bioactivity values and the values predicted by the model, whereas the RMSE value is the depiction of error between the mean of experimental and predicted activity values. Even for models with large R^2 value (that is ≥ 0.7), values of χ^2 and RMSE should be lower than 0.5 and 0.3 respectively, for good predictive ability of the model (Veerasamy *et al.*, 2011).

Cross validation

Cross validation approaches for internal validation include Leave-Group-Out (LGO), which involves leaving of a molecule or a group of molecules while creating model and evaluating the predictability of the model using the molecules left. Some of the important measures used in the internal cross validation of QSAR models are listed below.

Leave-One-Out (LOO) cross validation

In LOO cross validation, one compound is left out and the QSAR model is constructed using remaining compounds. The eliminated compound is used as a test for the predicted model. This process is repeated eliminating each of the compounds in the dataset one by one. The results so obtained from this are used for estimation of parameters involved in validation metrics. The predictability of the model is assessed by Predicted Residual Sum of Squares (PRESS) and cross-validated R^2 (Q^2) when Standard Deviation of Error of Prediction (SDEP) is obtained from PRESS (Roy and Kar, 2015; Roy *et al.*, 2015b).

Leave-Some-Out cross validation

In case of Leave-Some-Out (LSO) or Leave-Many-Out (LMO) a set of data compounds are eliminated and models are created with rest of the compounds. The left out compounds are then used to check the predictability of the model. Similar to LOO approach, LMO approach also involves repetitive cycles of elimination and model creation until each and every compound has been treated as a test set (Veerasamy *et al.*, 2011; Kar and Roy, 2011; Roy *et al.*, 2015b). On completion of all cycles of model training and testing, overall LMO- Q^2 value is calculated based on the compounds' predicted activity values. LMO methods is more consistent as compared to LOO (Veerasamy *et al.*, 2011).

Value of Q^2 is usually smaller than value of R^2 . In order to avoid over-fitting of the model, the difference between R^2 and Q^2 should not exceed 0.3. Over-fitted model may very well predict the activity of compounds for training set but for new compounds predictivity is compromised (Veerasamy *et al.*, 2011).

True Q^2 and r_m^2 metrics

True Q^2 proposed by Hawkins *et al.* is used for small data sets and r_m^2 metric is calculated based on the scaled values of observed and predicted activity. Q^2 should not be treated as an ultimate proof for good predictability of models. Value of Q^2 higher than 0.5 should not be interpreted as high predictive power of QSAR models; until the ability of model to predict the activity of large number of compounds that are not used for training of model is tested (Golbraikh and Tropsha, 2002). Some of the other metrics used for internal validation are true r_m^2 (LOO) and Y-Randomization, a metric for chance correlation. The true r_m^2 (LOO) metric reveals external validation characteristics as its value is derived from the model developed after repetitive cycles of LOO. Y randomization test involves process randomization and model randomization to validate the model by permuting the response values with respect to unaltered matrix (Roy *et al.*, 2015b).

Validation metrics for external validation

The validation metrics employed in external validation are as following:

- Predictive R^2 that can also be given as $Q^2_{(F1)}$ says about the correlation of observed and predicted data. Model is said to have good predictive power if the value of $Q^2_{(F1)}$ is greater than 0.5 (Roy *et al.*, 2015b).
- $Q^2_{(F2)}$ and $Q^2_{(F3)}$ using the mean of test data set and training data set respectively (Schüürmann *et al.*, 2008). For validation of QSAR model, threshold value of 0.5 is defined for both metrics (Roy *et al.*, 2015b).
- Golbraikh and Tropsha's criteria puts forth condition for selection of training and test data sets. For having a good predictive power, QSAR model should satisfy following conditions (Golbraikh and Tropsha, 2002; Veerasamy *et al.*, 2011):
 - $Q^2_{\text{training}} > 0.5$
 - $R^2_{\text{test}} > 0.6$
 - $(r^2 - r_0^2)/r^2 < 0.1$ or $(r^2 - r_0'^2)/r^2 < 0.1$, where r_0^2 is R^2 of predicted *vs.* observed activities and $r_0'^2$ is R^2 of observed *vs.* predicted activities.
 - $0.85 \leq k \leq 1.15$ or $0.85 \leq k' \leq 1.15$, where k and k' are the slopes of regression lines through the origin.
- Other metrics includes Root Mean Square Error of Prediction (RMSEP) to calculate prediction error of QSAR model (Roy *et al.*, 2015b); Concordance Correlation Coefficient (CCC), the most restrictive and precautionary measure, with ideal value of 1 (Chirico and Gramatica, 2011); r_m^2 (rank) which makes rank order predictions (Roy *et al.*, 2015b); and r_m^2 (test) to understand the relationship between observed and predicted values (Roy and Mitra, 2011; Roy *et al.*, 2015b).

Validation Metrics for Classification-Based Methods

The validation matrix employed in classification-based methods is the Wilks lambda (λ) statistics. It is used to test the significance of discriminant model function and is calculated as the ratio of within-category sum of squares to total dispersion. The value ranges between $0 < \lambda < 1$, with lower value corresponding to higher level of discrimination. Further, canonical index (Rc) is used to estimate the strength of relationship between various dependent and independent variables; Chi-square (χ^2) to check the quality of the classification based model; and Squared Mahalanobis distance is a measure calculated using random data points (Roy and Mitra, 2011; Roy *et al.*, 2015b).

Interpretation & Applicability Domain Analysis

The parameters or descriptors used in the model should be interpretable. Mechanistic interpretation of the built QSAR model helps in understanding the influence of descriptors in the predicted activity. Applicability domain analysis helps us to understand whether the built QSAR model can be used for any set of compounds. The applicability domain model is built on the theoretical region present in the chemical space of descriptors and activity modeled. It enables to understand the feasibility of activity or response prediction by the constructed QSAR model for a given set of compounds. So, the QSAR model prediction for a set of compounds is only reliable if the chemical space or applicability domain of those compound falls within the applicability domain of the compounds used for training the model (Roy *et al.*, 2015b). The theoretical region in the chemical space is identified or estimated by different methods. Application domain assessment is done through probability density distribution, geometrical

methods, distance-based methods, ranges in descriptor space when descriptor space are used, and the range of response variable when modeled response space is used (Jaworska *et al.*, 2005).

Multidimensional QSAR

QSAR started with 0D and has evolved to 6D. Each dimension arose as a need to overcome the limitations of previous dimensions and to be more advantageous than the former. 1D QSAR calculated the molecular properties such as electronic, hydrophobic, steric and so forth. 2D QSAR considers geometric parameters, topological indices, molecular fingerprints, polar surface area but it excludes steric properties. 3D QSAR technique focuses on the spatial properties of the compound. So, the drawbacks of 2D QSAR get addressed in 3D QSAR method. The descriptor methods used in 3D QSAR are alignment-dependent and alignment-independent. The alignment dependent methods are Comparative Molecular Field Analysis (CoMFA), Comparative Molecular Similarity Indices Analysis (CoMSIA), Comparative Binding Energy Analysis (CoMBINE), Comparative Residue Interaction Analysis (CoRIA), Hint Interaction Field Analysis (HIFA) and so forth. The alignment independent methods include Comparative Molecular Moment Analysis (CoMMA), Comparative Spectral Analysis (CoSA), and Holo-QSAR (HQSAR). 3D QSAR employs methods like Artificial Neural networks (ANN), Partial Least Squares Method (PLS), cluster analysis, and principal component analysis, and others for descriptor selection makes it more powerful than 2D QSAR. Even then, the 3D QSAR technique faces difficulties when there are large numbers of compounds in the data set, and has to compromise with the prediction accuracy. To overcome these drawbacks, 4D QSAR evolved. 4D-QSAR with fourth dimension of ensemble sampling addresses the issues of 3D QSAR. It includes descriptors for gird occupancy measures. 4D-QSAR can be applied for both, receptor independent and receptor dependent analysis (Hopfinger *et al.*, 1997). Further, 5D-QSAR evolved with the addition of new dimension to the 4D-QSAR, the new dimension being the multiple ligand topology representations. Ensembles of multiple representations deployed in 5D-QSAR makes this approach less biased when compared to 4D QSAR (Vedani and Dobler, 2002). 6D-QSAR improves the former 5D-QSAR strategy by including another dimension for solvation function that helps in analyzing different solvation models (Polanski, 2009).

QSAR in Drug Designing and Discovery

Drug design and discovery is a laborious and time-consuming process. It takes roughly 10–12 years for a molecule to be identified and approved as a drug. Most of the drugs fail during pre-clinical and clinical trials. The cost of drug discovery is very high. Determining drug candidates through QSAR studies would reduce cost of production and failure at an early stage. QSAR approaches help in identifying hits from a large library of compounds. The identified hit molecules can be purchased and studied for activity through experiments (Tang *et al.*, 2009; Montero-Torres *et al.*, 2006). The molecules with proven activity can be further optimized to design promising drug candidates. Thereby, QSAR studies avoid synthesis and testing of large number of compounds saving enormous time and cost.

Case Studies

A number of success stories reflecting the potential of QSAR in building reliable models have been reported in the literature. We have discussed here a few studies that dealt with a wide range of problems to get insights into the applications of QSAR approach.

The first example presented here is a QSAR model for designing better drugs for combating cancer. Apoptosis is an important process that can decide the fate of a cell. Malfunctioning of the process with atypical expression of B-cell lymphoma-2 (Bcl-2) anti-apoptotic proteins is a promising hallmark of cancer and in most of the cases results in resistance to chemo and radiotherapy. Multiple approaches including antisense oligonucleotides (ASOs), peptides and small molecule inhibitory compounds have been designed against these anti-apoptotic proteins. However, low cost and easy delivery makes small molecules a method of choice. To develop better compounds on the basis of available information, various QSAR models have been generated. But these models are limited to a single scaffold. In one such study, attempt was made to develop QSAR models for seven different classes of inhibitors reported in literature targeting Bcl-2 and Bcl-xL (Kanakaveti *et al.*, 2017). 453 such small molecule inhibitors with known IC_{50} (ranging from 1 nM to 100 μ M) were grouped into seven categories comprising of Apogossypol (89 compounds), Quinazoline thione (51 compounds), Pyrazole pyrimidine phenyl acyl (110 compounds), Quinolone (56 compounds), Thiomorpholine (42 compounds), Benzothiazole hydrazine (78 compounds) and Polyquinoline (27 compounds) depending upon the core structure. A total of 787 features (including constitutional, topological, electrostatic, geometrical and physicochemical descriptors) were tested. The most relevant descriptors were chosen and fitted using multiple linear regression analysis. Two to three parametric models were generated for all the different classes of compounds. ($n - 1$) and ($n - 10$) leave-out cross validations were used to evaluate the performance of the generated models. The QSAR analysis resulted in models showing Pearson correlation coefficient ranging from 0.95 to 0.985. Three already known inhibitors- ABT-199, Navitoclax and Sabutoclax were tested against their generated models. The predicted IC_{50} was comparable to the reported activity. A correlation between pIC_{50} and pKi ($-\log Ki$) was delineated and also found commonalities in the activity shown by the seven families with respect to structural disparities using an

approach called similarity-descriptor coupling. The study has been translated into a user-friendly webtool to predict a pan or specific inhibitor for Bcl-2 and Bcl-xL targets (Kanakaveti *et al.*, 2017).

This second example illustrates how pharmacokinetic properties of drug molecules can be predicted using QSAR modeling. Penetration through blood brain barrier (BBB) is one of the most important features that reflect the drug-likeness of small molecular compounds. Drugs designed for central nervous system should be able to cross this barrier however penetration of BBB by peripherally acting drugs should be minimize to avoid side effects. So estimation of pharmacokinetic properties of candidate compounds *in silico* before testing them experimentally can save enormous time and money. In this study, a set of 529 organic compounds was used to correlate their chemical structures and distribution coefficients between the brain and blood using artificial neural networks. The molecular structures were defined in terms of occurrence of number of various types of fragments containing up to 10 atoms. Out of all the fragment descriptors, the most important ones were selected using the stepwise multiple linear regression. It was seen that the best model was based on the fragments comprising up to nine atoms. The model was further validated using a dataset of 2053 compounds, which was categorized as BBB+ (penetrating) and BBB- (non-penetrating). The constructed model could correctly classify 90% of BBB+ compounds from a test set, however the prediction specificity for BBB- category was low. Some of the features that have the strongest positive effects on the LogBB included hydrophobic fragments like alkyl or aromatic and presence of hydroxyl group in α - position to the carbonyl group. On the other hand, it was found that permeability decreases if the structure contains strongly polar groups like hydroxyl, carboxyl, and guanidine. This model has been integrated into a web service for predicting ADMET parameters of drugs developed in the Laboratory of Medicinal Chemistry, Department of Chemistry, Lomonosov Moscow State University (Dyabina *et al.*, 2016).

With increasing industrialization, degradation of pollutants has become a crucial need to keep the environment clean. Benzene and its derivatives are the most common chemical structure found in the nature. It is also a structural part of degradation intermediates of complex pollutants like pesticides, pharmaceuticals, surfactants or synthetic dyes. However, the chemical properties deciding their environmental fate and behavior depends on the type, number and position of functional groups present at substitution sites. Here QSAR proved to be a fast and reliable approach for testing the degradation of aromatic compounds. Thirty six congeneric single-benzene ring compounds with known biodegradability were divided into training and test sets (24 and 12 compounds, respectively). The semi-empirical quantum-chemical descriptors like dipole moment, energy of the highest occupied molecular orbital (EHOMO), energy of the lowest unoccupied molecular orbital (ELUMO), energetic difference between EHOMO and ELUMO, final heat of formation and ionization potential, and various other molecular descriptors were calculated using various software. The correlation between descriptors and biodegradability prior and at half-life was obtained using variable selection Genetic Algorithm and Multiple Linear Regression Analysis methods. The validation of best-selected models based on statistical parameters was performed using Leave Many Out and "Y-scrambling" tests. The generated models were thus used to study the key structural features that influence the biodegradability of the compound of interest and correlate to its degradation mechanisms by UV-C/H₂O₂. Molecular mass, number of C-C bonds determining the rate of saturation of benzene ring making it susceptible to cleavage into more readily degradable aliphatic compounds, electron donating/withdrawing groups, symmetry of the molecule, presence of sulfo-group, ionization potential and electrotopological states were some of the important descriptors related to the biodegradability of aromatic compounds in water. The potential of such models can be extended to more extensive purposes like risk assessment studies (Cvetnic *et al.*, 2017).

In the following example, structural factors of ionic liquids (ILs) have been correlated with the process of micelization. Critical Micelization Concentration (CMC) of any ionic liquid depends upon the types of ions it possess. Micelization affects the synthesis, purification and regeneration routes of these ionic liquids and thus is an important feature to be considered. In this study, an attempt was made to derive a qualitative relationship between structural features of ions and their effect on micelization of ILs. It was also verified whether the micelization process is governed by the constituent ions separately or they have additive effects. Literature was explored to collect experimental data of ILs with their CMC. A dataset of 59 structurally diversified IL's with the CMC ranging between the 0.098 and 902 mM was prepared. 42 compounds were used to train the model while rests were used for testing. Various molecular descriptors were generated using DRAGON software and the most appropriate ones were chosen using genetic algorithm implemented in QSARINS software. The correlation between the descriptors and CMCs was derived using Multiple Linear Regression (MLR) technique. Various statistical parameters like determination coefficient, Concordance Correlation Coefficient, Root Mean Square Error, Mean Average Error and F-value were used to evaluate the fitting of model and its significance. The leave-one-out and Y-scrambling approach were used for internal validation and investigating the robustness of the generated model. An altogether new test data set was used for external validation. Decrease in CMC was attributed to less spherical, improperly folded cations containing larger hydrophobic domain. For anions, bigger size was associated with decrease in CMC. Also the effect of cations and anions in determining the CMC was found to be independent of each other (Barycki *et al.*, 2017).

People today have become more careful about their eating habits to adopt a healthy life style. They avoid overconsumption of high-calorific food to reduce the risk of various metabolic disorders, cardiovascular diseases, obesity and diabetes. Sugars or saccharides are major contributors in this. Industry is focusing on finding out new compounds, natural or synthetic, with low calories but high sweetness. There are various QSAR models in the literature that help in extracting various structural features responsible for imparting the sweetness to the compounds, or distinguishing between sweet and non-sweet compounds. A study was carried out for virtually screening known natural compounds using QSAR modeling for identification of new sweeteners (Chéron *et al.*, 2017). A database of 316 compounds belonging to seventeen chemical families and sweetness values ranging from 0.20 to 225,000 was created. The sweetness index for all the compounds was relative to sucrose. The protonation state of compounds was adjusted according to the pH value of saliva, i.e., 6.5. Descriptors were calculated for both 2D and 3D structures of

compounds using Dragon software. Random Forest and Support Vector Regression, machine learning algorithms were used to generate the models. Training set consisted of 225 molecules while the test set had 91 molecules. Leave-one-out cross-validation methods were used for both 2D and 3D QSAR models. Additional filters to avoid undesirable properties like bitterness and toxicity were applied. It was found that majority of the identified natural sweeteners were from terpene family, less than 200 molecules belonged to the category of saccharides, polyphenols or phenylpropanoids. The most potent natural sweeteners were based on saponin and stevioside scaffolds, with 1000–10,000 times more sweetness than sucrose (Chéron *et al.*, 2017).

Biographical Sketch

Swathik Clarancia Peter received her M.Tech. in Computational Biology from Pondicherry University, India in 2017 and B.Tech. in Bioinformatics from Tamil Nadu Agricultural University, Coimbatore, India in 2015. At present she is working as a senior research fellow in ICAR-Sugarcane Breeding Institute, Coimbatore, India. She works in the field of drug design & discovery and transcriptome data analysis.

Mannu Jayakanthan is an Assistant Professor in the Department of Plant Molecular Biology and Bioinformatics at Tamil Nadu Agricultural University, Coimbatore, India. He obtained his PhD from Pondicherry University and pursued his postdoctoral fellowship at the Centre for Cellular and Molecular Biology (CCMB) in Hyderabad, India. His research interest lies in computer-aided drug discovery.

Jaspreet Kaur received her M.Tech. in Bioinformatics from Delhi Technological University, India in 2013, and B. Tech. in Biotechnology from Amity University, India (2011). She joined Indian Institute of Technology, Delhi, India in 2014 for the Ph.D. program. She works in the field of computer aided drug designing and devising computational approaches for aiding in targeted genome editing.

Vidhi Malik received her M.Tech. in Bioinformatics from Delhi Technological University, India in 2013 and B. Tech. in Biotechnology from Sardar Vallabhbhai Patel University of Agriculture and Technology, India in 2011. She joined Indian Institute of Technology, Delhi, India in 2015 for the Ph.D. program. Her research interest lies in next generation sequence (NGS) data analysis and computer-aided drug designing.

Navaneethan Radhakrishnan received his B.Tech. in Bioinformatics from Tamil Nadu Agricultural University, India in 2016. He joined Indian Institute of Technology Delhi, India in 2016 as Junior Research Fellow in the Department of Biochemical Engineering and Biotechnology. His research interest lies in understanding the biological systems using computational approaches.

Durai Sundar is a DuPont Young Professor in the Department of Biochemical Engineering and Biotechnology at Indian Institute of Technology, Delhi. He obtained his education from Pondicherry University and Johns Hopkins University, Baltimore, United States. He is a specialist in molecular and computational biology and his current research interests are in rational design of genome editing tools and in the biological activity of natural drugs.

Pharmacophore Development

Introduction

Discovery of new drug molecules is an ever challenging task, even until today. It is a fact that the success rate in this area is extremely low. Typically, only one out of a million compounds finally obtain approval to be used as a drug. Starting from the process of target identification, a huge investment (approximately 2 billion dollars) and a long period (ranging 8–16 years) in research and development (R&D) activities are normally required to yield a new drug. After the post-marketing surveillance (phase 4 of the clinical trials), if the drug is found to have any adverse effects, it would be withdrawn from the market with a loss which amounts to about million dollars. Hence, the entire process starting from the drug discovery to design is a risky affair and within a short period of time, the pharmaceutical companies may need to take back the revenue out of their investment. Hence, there is an enormous pressure on pharmaceutical industries to come up with new drug molecules to treat existing diseases. Moreover, the environmental changes around the globe have heavily contributed to the evolution of drug-resistant strains; therefore, there is an urgent need for alternate/new more effective drugs.

Computer-aided drug design (CADD) tools have assisted medicinal chemists to a large extent by reducing the time, cost and number of compounds to be synthesized as leads. In this computational approach, the integrated aspects of chemistry (ligands) and biology (proteins/enzymes/receptors) are studied in order to search for new drug candidates. Currently, 20% of pharmaceutical R&D expenditure is allotted to CADD segment which helps face various challenges encountered during the R&D of new drugs. Further, the computational drug design is based on two major approaches namely, structure-based drug designing (SBDD) and ligand-based drug designing (LBDD). SBDD approach uses the structural information of the target proteins like enzymes or receptors, to identify compounds that can potentially be used as a drug (Kalva *et al.*, 2016; Agrawal *et al.*, 2016; Agrawal *et al.*, 2018). On the other hand, the ligand-based approach involves the development of 3D pharmacophore models and modeling quantitative structure-activity relationship (QSAR) or quantitative structure-property relationship (QSPR) (Balakumar *et al.*, 2017; Bheemanapalli *et al.*, 2013). This involves using the physicochemical properties of the ligand molecules for drug development. The 3D pharmacophore modeling is one of the useful drug design approaches in new drug discovery process.

Definition of a Pharmacophore: Initially, the term pharmacophore was used to refer to – “chemical groups” of a molecule that are responsible for a biological effect (Güner and Bowen, 2014). However, with time its meaning has shifted to patterns of “abstract features” that are responsible for a biological effect. The basis of modern day International Union of Pure and Applied Chemistry (IUPAC) definition of a pharmacophore is a redefinition of the above statements as given by Schueler (1960). The IUPAC definition is as follows:

“A pharmacophore is an ensemble of steric and electronic features that is necessary to ensure the optimal supramolecular interactions with a specific biological target structure and to trigger (or to block) its biological response.”

This is the modern accepted definition of a pharmacophore, presently (Güner, 2000; Wermuth *et al.*, 1998). Pharmacophore modeling has a wide range of applications in drug design and discovery such as 3D database search, scaffold hopping, virtual screening, ligand profiling, pose filtering, fragment designing and predicting the biological activities. Most commonly observed features in pharmacophore models are hydrogen bond donors, hydrogen bond acceptors, aromatic rings, hydrophobic sites, positively ionizable groups and negatively ionizable groups.

Historical Perspective of Pharmacophore Modeling

Paul Ehrlich, the father of chemotherapy, initially conceptualized the pharmacophores and that concept is still unperturbed for the past century (Ariens, 1966; Ehrlich, 1909, 1898). In simpler words, the bioactive molecules interact with their targets via a 3D arrangement of abstract features that define interaction types rather than specific functional groups. These interaction types could be the formation of hydrogen bonds, charged interactions, metal interactions, or hydrophobic and aromatic contacts (Qing *et al.*, 2014). Using this knowledge compounds with desired biological activities have been synthesized. The earliest success of a 2D pharmacophore model was demonstrated by synthesizing *trans*-diethylstilbestrol (an estrogenic agent) based on the pharmacophore similarities with estradiol even though the latter had a non-planar conformation (Fig. 1; Dodds and Lawson, 1938). Similarly, an anti-hypertensive drug called clonidine (Fig. 2) was found to interact with the central norepinephrine receptor through 3-point attachment (an ionic bond, hydrogen bond and stacking interaction) (Andén *et al.*, 1970). Though norepinephrine and clonidine had different chemical structures, they retained common features exhibiting functional similarities. Another important discovery in this regard was the determination of critical intramolecular distances from protonated nitrogen (N^+) to the aromatic ring ($D=5.1\text{--}5.2\text{ \AA}$) and for the elevation of the positive charge to the aromatic plane ($H=1.2\text{--}1.4\text{ \AA}$) (Pullman *et al.*, 1972).

Fig. 1 Structural comparison between estradiol and *trans*-diethylstilbestrol.

Fig. 2 (a) Clonidine presents the same type of molecular interactions as nor-epinephrine despite the difference in the orientation of the imidazolidinium ring towards the phenyl ring. (b) 3D structures of nor-epinephrine (cyan) and clonidine (grey) (c) 3D overlay of nor-epinephrine (cyan) and clonidine (grey).

Pharmacophore Modeling Approaches

Two types of pharmacophore modeling techniques are employed in drug design, namely, ligand-based pharmacophore modeling and structure-based pharmacophore modeling. This section describes the two different approaches used for pharmacophore modeling.

Ligand-Based Pharmacophore Modeling

If the target protein structure is not available, then the ligand-based pharmacophore modeling approach is employed for the design of new chemical entities (NCE). Two important steps of the ligand-based pharmacophore modeling are

1. Feature analysis in the training set molecules/ligands, and
2. Alignment of all bioactive conformations of the ligand to establish better overlay of features.

Currently, many automated software and tools (**Table 1**) for pharmacophore model generation are available for example, HipHop and HypoGen (Catalyst software packaged as a part of BIOVIA Discovery Studio Dassault Systems, 2016), DISCO (Martin *et al.*, 1993), GASP (Jones *et al.*, 1995), GALAHAD (Richmond *et al.*, 2006), PHASE (Dixon *et al.*, 2006), MOE (Molecular Operating Environment MOE, 2017) and several other free academic programs (Bandyopadhyay and Agrafiotis, 2008; Baroni *et al.*, 2007; Nettles *et al.*, 2007). Each program differs in its algorithm that handles the generation and validation of pharmacophore models. There are several challenges and hurdles that one faces during pharmacophore development. For example, bioactive conformations of the compound may be unknown, then conformational flexibility remains one of the significant hurdles in developing a pharmacophore model. Another challenge is the molecular alignment of the ligand conformations in the training set.

Pharmacophore alignment: Molecular alignment can be classified into two types namely, point-based or property-based approaches (Wolber *et al.*, 2008). Atoms or chemical feature point distances are minimized in the point-based approaches whereas the property based approaches use molecular field descriptors to generate alignments. Point-based alignment algorithms have been used by a majority of the programs. The point-based method can be further categorized based on whether points represent atoms, fragments or chemical features. Each of the points can be superimposed using a least-squares fitting method. However, these assumptions become one of the greatest limitations for the all point-based methods while aligning dissimilar ligands.

On the other hand, molecular field descriptors or Gaussian functions are used for the property-based algorithms for the alignments. The stochastic proximity embedding, atomic property fields, fuzzy pattern recognition and grid-based interaction

Table 1 Some commercial tools and web servers for pharmacophore development

Software	Brief description	Web link
GASP	• Uses a genetic algorithm for pharmacophore identification. • GASP finds similarity between functional groups in different molecules and the alignment of these groups in a common geometry. • GASP is accessible through the SYBYL molecular modeling package.	https://www.certara.com/pressreleases/certara-enhances-sybyl-x-drug-design-and-discovery-software-suite/
CATALYST	• Identifies promising new molecular entities with or without target-structured data. • CATALYST is a part of the BIOVIA Discovery Studio.	http://accelrys.com/products/collaborative-science/biovia-discovery-studio/pharmacophore-and-ligand-based-design.html
MOE pharmacophore modeling	• MOE can perform ligand, structure and fragment based pharmacophore modeling. • MOE Pharmacophore methods use a generalized molecular recognition representation and geometric constraints.	https://www.chemcomp.com/MOEPharmacophore_Discovery.htm
PHASE	• Phase uses a newly developed common pharmacophore perception algorithm. • Uses pharmacophore-based shape alignments to quickly create high-quality hypothesis from a handful to hundreds of known active ligands. • PHASE is accessible through Schrodinger molecular modeling package.	https://www.schrodinger.com/phase
PharmaGist	• PharmaGist is a freely available web server for ligand based pharmacophore identification. • PharmaGist server calculates candidate pharmacophores by multiple flexible alignments of the input ligands.	http://bioinfo3d.cs.tau.ac.il/pharma/about.html
PharmMapper	• PharmMapper freely available web-server designed to identify potential target candidates for the given probe small molecules.	http://lilab.ecust.edu.cn/pharmmapper/help.php
ZINCPharmer	• PharmMapper uses semi-rigid pharmacophore mapping protocol. • ZINCPharmer is free pharmacophore search software for screening the purchasable subset of the ZINC database. • Uses the Pharmer open source pharmacophore search technology to efficiently search a large database of fixed conformers for pharmacophore matches.	http://zincpharmer.csb.pitt.edu/

energies are the recently developed alignment methods (Bandyopadhyay and Agrafiotis, 2008; Baroni *et al.*, 2007; Nettles *et al.*, 2007; Totrov, 2008).

Appropriate selection of the training set is another crucial step in the generation of a valid pharmacophore model. When a different training set is employed for the pharmacophore generation using the same software program, it usually results in entirely different models (Hecker *et al.*, 2002; Toba *et al.*, 2006; Vadivelan *et al.*, 2007). For example, three different pharmacophore models were proposed for cyclin-dependent kinase 2 (CDK2) inhibitors bearing different features and location constraints using the same software program Catalyst (now a part of BIOVIA Discovery Studio Dassault Systems, 2016; Vadivelan *et al.*, 2007).

The ligand-based pharmacophore models can be developed in either qualitative (common feature-based hypothesis) or quantitative (3D-QSAR based models) manner. Below we describe each of the approach in brief.

Qualitative Models: The qualitative model is based on common feature pharmacophore generation from a set of bioactive ligands/training set (usually 2–16 ligands) of diversified structures. In the qualitative model, we assume similar binding modes for the training set with the same target protein and the 3D spatial arrangements of chemical features shared among the training set ligands is deduced. In this common feature-based hypothesis, explicit biological activity data is not required, partial matches are allowed with the preference of structural diversity among the ligands. Commonly used software like Hip-Hop, Phase, and MOE analyse ligands based on their chemical features and superimpose all the features to identify a specific conformation (Dassault Systems, 2016; Dixon *et al.*, 2006; Molecular Operating Environment MOE, 2017).

Quantitative Models: In case of the quantitative model, the biological activity data (*e.g.*, IC_{50} or K_i) are required while generating the predictive hypothesis to correlate chemical structure with biological activity thereby predicting the activity of novel compounds. The three important phases namely constructive, subtractive and optimization are involved in the generation of a quantitative pharmacophore model. Appropriate alignment is the key factor that decides the prediction power of a 3D quantitative model for virtual screening tasks. In this approach, a training dataset of 18–30 ligands depicting appropriate structural diversity with their pharmacological activity data are required (as represented by IC_{50} , EC_{50} , or K_i values of similar assay conditions). As the quality of a pharmacophore model and its predictability depends on the training data set, it is very crucial to have ligands with a wide range of biological activity in the training dataset. The activity could span over four orders of magnitude comprising categories of most active, moderately active, least active ligands and decoys. Commonly used software such as Hypogen, Phase-Macromodel and MOE are widely used for the generation of 3D-QSAR pharmacophore models (Dassault Systems, 2016; Dixon *et al.*, 2006; Molecular Operating Environment MOE, 2017). A 3D-conformational search is performed for each of the ligands within an energy range to yield multiple conformers using an appropriate algorithm. These algorithms consider coverage of the energy landscape and diversity among the conformational models of the ligands under study. Other algorithms implemented in commercial software programs are (Rubicon Daylight Chemical Information Systems, Inc.), (Omega, OpenEye Scientific Software) and stochastic proximity embedding (SPE) (Agrafiotis *et al.*, 2013).

Structure-Based Pharmacophore Modeling

The term structure in 'structure-based pharmacophore modeling' refers to the 3D structure of a macromolecule which is usually a receptor or an enzyme with or without a bound ligand. This structure is determined through X-ray crystallography or nuclear magnetic resonance (NMR) spectroscopy techniques or may be constructed using homology modeling (Vyas *et al.*, 2012). If the protein structure is available as a potential drug target, then structure-based pharmacophore modeling will be preferred as this approach considers interaction points within the protein binding site. This method involves key aspects such as protein preparation, identification or prediction of ligand binding site, pharmacophore feature generation and selection of crucial features contributing to the pharmacological activity. In this approach, protein structure is the crucial source of information whether obtained from protein data bank (PDB) or modeled using a suitable template by homology modeling. The second most important step is the binding site prediction which is performed using different algorithms. To distinguish the binding site from other parts of the protein surface, most of these methods have exploited one or more of the following properties namely, evolutionary, geometric, energetic, statistical, and combined or knowledge-based methods (Xie and Hwang, 2015). After a careful analysis of the binding site, the programs identify the complementary chemical features of the binding-site amino acid residues and their spatial arrangements to derive a meaningful pharmacophore model. These programs initially generate interaction maps and convert them into several pharmacophoric features. This methodology yields several chemical features which must be optimized using customized tools implemented in the respective software programs. This task can be accomplished using approaches like clustering of features, removing certain unimportant features, comparing the features which complement the docked pose of ligands, and site-directed mutagenesis data. Finally, the key features responsible for contributing the desired pharmacological response will be carefully selected. For structure-based pharmacophore modeling, software programs like BIOVIA Discovery Studio (Dassault Systems, 2016), Sybyl (SYBYL7.3 Tripos Inc, 2003), MOE (Molecular Operating Environment MOE, 2017), Chemogenomics (Bredel and Jacoby, 2004), GBPM (Ortuso *et al.*, 2006), LigandScout (Wolber and Langer, 2005), Schrodinger-Maestro (Schrodinger, 2017), Pocket v2 (Chen and Lai, 2006), and Snooker (Sanders *et al.*, 2011) are commonly employed.

If the protein exists in its ligand-bound form, the key interaction points between these two can help derive at the pharmacophore model. To construct the structure-based pharmacophore model from the complex, the ligand is initially hybridized and the bonds are characterized. A widely employed program for this purpose is LigandScout (Wolber and Langer, 2005). It uses a heuristic approach along with the template-based numeric analysis of the protein-ligand complex which may have been obtained

through PDB or the docking procedures. According to the protein-ligand binding information, a consensus model will be derived either by overlaying all the obtained models or by model refinement procedures.

Two major drawbacks associated with structure-based pharmacophore modeling are protein flexibility and conformational flexibility of the ligand. To overcome these drawbacks, two approaches can be used (1) deriving a model from the docked complex obtained through a flexible docking of ligands into the protein binding-site; (2) building and aligning the models simultaneously from the different snapshots of the protein or protein-ligand complexes of molecular dynamics (MD) simulations (Drwal and Griffith, 2013).

The energetically optimized structure-based pharmacophores (e-pharmacophores) can be used to screen millions of ligands as implemented in Schrodinger software (Therese *et al.*, 2014). These-pharmacophores remove the requirement of known active ligands while generating pharmacophore models and assist in identifying new regions of the active-site for drug design. In this protocol, the fragment docking (Glide XP Friesner *et al.*, 2004, 2006) data will be used to generate the hypotheses for each conformation using the e-pharmacophore script. This script maps the Glide XP energies for the top 2000 docked poses onto the ligands aligned to the receptor conformations followed by the clustering of the fragments. The software, Phase (Dixon *et al.*, 2006), will be used to generate the hypotheses from the docked poses with default features.

Role of Excluded Volumes in Pharmacophore Modeling

The so-derived pharmacophore model may possess the requisite features to bind to the target protein but yet fail to bind. One factor that may be responsible for this observation is the steric clashes between the ligand and the receptor. In such cases, the quality of the generated model can be improved by incorporating exclusion volume constraints. Ligand excluded surface represents an approximation of the regions accessible to the ligand under consideration. Receptor-based excluded volumes are represented as spheres centred on appropriate atoms in and around the binding site, with sizes dictated by the associated atomic van der Waals radii. If the ligand maps all the key features of the model, it is considered as active whereas if the functional groups of the ligand overlap the excluded volume regions, it will be inferred as pharmacologically inactive ligands. In some cases, this excluded volume constraint plays a crucial role in identifying potent ligands which match exclusively essential pharmacophoric features without occupying the exclusion volume (Schuster *et al.*, 2006).

A hard-sphere approximation is usually encountered while employing an exclusion volume in the model. In cases of inadequate sampling, this approximation may be deemed as too strict. Therefore, this approximation can be relaxed by customizing the excluded volume in the following ways

- (1) Decreasing the size of the spheres,
- (2) Removing spheres that are in close proximity to the bound ligand, and
- (3) Tolerating a certain amount of overlap between the ligand and the excluded volumes.

In case of ligand-based pharmacophore modeling, when the receptor structure is unavailable, assigning meaningful excluded volumes is not so easy. However, this limitation may be overcome by inferring the excluded volumes from a set of known active ligands (Shrink-Wrap Method Van Drie, 1997) or inactive ligands (Murray *et al.*, 1999). Various software packages allow either manual or automated placement of excluded volumes based on a visual inspection of aligned structures and generate spheres at the desired locations.

The quality of the generated pharmacophore models can be assessed based on a scoring and ranking to determine how well the ligands map onto the pharmacophore model. A higher ranking indicates a better reliability and quality.

Validation of Pharmacophore Models

Once a pharmacophore model has been generated, it must be validated to ascertain its reliability and quality for successive applications in different molecular modeling tasks. To test whether or not our models are good enough to predict the active compounds, we perform pharmacophore validation. For the identification of a valid model, various validation parameters are analyzed through statistical analysis, the goodness of hit list (GH), receiver operating characteristic (ROC) curve, test set prediction, cost analysis (Hypogen), and Fischer's randomization test (Hypogen). This helps in differentiating the active ligand from inactive ligands for the specified drug targets. Below we discuss these analyses in brief.

Statistical Analysis

A regression analysis of the model can be performed against the test set ligands to verify a pharmacophore model. If the pharmacophore model demonstrates the correlation of $r^2 > 0.7$ between the predicted activity data and experimentally reported data, it is considered to be a valid model. To perform this task, a test set of ligands is constructed all of which act on the same target as that of training set ligand. The test set is classified as most active, moderately active, and less active based on the available range of the activity data to understand the predictability of the generated pharmacophore model.

Güner-Henry (GH) Method

The Güner-Henry method is a commonly employed validation protocol to score the hit lists and provide a quantitative "goodness of hit list" (GH) score. While using qualitative data, our aim is to identify and retrieve the maximum possible number of

molecules that have the same activity as the target structure and to simultaneously minimize the number of inactive molecules. Güner and Henry introduced the GH score to evaluate the effectiveness of 3D database searches and can be applied to the evaluation of any sort of search for which qualitative bioactivity data are available (Willett, 2004). It helps in the retrieval of active ligands from a large pool of ligands that includes inactive and decoy ligands as well. For this analysis, a dataset is built using inactive ligands from the literature or from the database of decoys (DUD-E) tools (Mysinger *et al.*, 2012). These decoys are mostly less active/inactive ligands that resemble ligands physically but are topologically dissimilar to minimize the likelihood of actual binding at the same time (Mysinger *et al.*, 2012). The value of GH score approaching 1 indicates an ideal model (Guner *et al.*, 2004). The following Eqs. 1–4 are used for calculation of GH score.

$$\text{Percent yield of actives (\%y)} = \frac{Ha}{Ht} \times 100 \quad (1)$$

$$\text{Percent ratio of actives (\%A)} = \frac{Ha}{A} \times 100 \quad (2)$$

$$\text{Enrichment factor (EF)} = \frac{Ha/Ht}{A/D} \quad (3)$$

$$\text{Goodness of Hit – list (GH)} = \left(\frac{HA}{4HtA} \right) \times (3A + Ht) \times \left(1 - \frac{Ht - Ha}{D - A} \right) \quad (4)$$

Here, D is total number of molecules in a database, A is total number of active molecules in a database, Ht is total hits, Ha is active hits, GH is goodness of hit score.

Receiver Operating Characteristic (ROC) Curve

The ROC plot (specificity vs sensitivity) is used to determine the ability of the generated pharmacophore to distinguish between active and inactive ligands. This can be represented as an area under the curve (AUC) and other relevant parameters such as true positives (TP), true negatives (TN), false positives (FP), and false negatives (FN) (Triballeau *et al.*, 2005). Ideally, AUC near to 1 demonstrates the perfection of the valid model. The formula to calculate the above-mentioned parameters are mentioned in the Eqs. 5–7.

$$\text{Sensitivity (Se)} = \frac{TP}{TP + FN} \quad (5)$$

$$\text{Specificity (Sp)} = \frac{TN}{TN + FP} \quad (6)$$

$$\text{Concordance} = \frac{TP + TN}{TP + TN + FP + FN} \quad (7)$$

Cost Analysis

The cost analysis method (as implemented in Hypogen, BIOVIA-DS program (Dassault Systems, 2016)) is used to analyse the statistical significance of the pharmacophore model in terms of fixed cost, null cost, and total cost. The fixed cost is the simplest model that fits all data while the null cost represents a high cost model with no features (Kandakatla and Ramakrishnan, 2014). The activity in the high cost model is determined as an average of the activity data from the training set compounds. For a valid pharmacophore model, ideally the total cost should be close to the fixed cost and the difference between the null and fixed cost value is large. A cost difference of 60 means, between 40 and 60 and below 40 means indicates a true correlation, 75%–90% and poor correlation (Kandakatla and Ramakrishnan, 2014). Similarly, configuration cost and error costs are also considered during the validation. The former refers to the complexity of the pharmacophore model space and the latter is represented by root-mean-square deviations (RMSDs) between the estimated and the experimental activities of the training set molecules. A valid pharmacophore model should comprise of good correlation, highest cost difference, and the lowest RMSD.

Fischer's Randomization Test

This test utilizes the Cat Scramble program of Catalyst/BIOVIA-DS (Dassault Systems, 2016) to create the random spreadsheets for the training set and reassign the activity values to each of the ligands to generate different pharmacophore models bearing same features. Models are generated at high ($\geq 95\%$) confidence level with a cost value lesser than the original pharmacophore model. This indicates that there is a 95% chance for the model to represent a true correlation which offers strong confidence in obtaining an accurate and reasonable pharmacophore model.

Applications of Pharmacophore Modeling

Pharmacophore modeling techniques are widely used in the qualitative and quantitative analysis of ligands to predict the pharmacological activity of hypothetical molecules (Böhm *et al.*, 2004; Sun *et al.* 2012). Hence, the pharmacophore modeling is a crucial and integral part of CADD approach in drug discovery projects. Once a pharmacophore model has been generated, it can be used for searching for potential ligands from a chemical database. Therefore, the pharmacophore model is used for 3D database search, scaffold hopping, virtual screening (VS), ligand profiling, pose filtering, fragment designing and predicting the pharmacological activities. Fig. 3 depicts various applications of pharmacophore modeling in drug design and discovery stages. A brief description of the applications of pharmacophore modeling is provided in the following subsections.

3D Database Search

A validated pharmacophore model can be used for searching bioactive molecules from a chemical database with a large number of chemical structures. The “hits” obtained can provide good candidates for the lead optimization processes. For the purpose of design and optimization of novel lead compounds, programs such as BUILDER and LUDI (Bohm, 1992; Roe and Kuntz, 1995) are helpful to search different scaffolds that possess the essential features of the generated pharmacophore model.

Scaffold Hopping

While determining the best candidate for drug development potential, hits are identified by high-throughput or virtual screening of corporate compound collections. The manipulation of the scaffold (or the core structure) of a hit molecule is much more complicated and associated with a considerable loss of activity (Zhao, 2007). That is why, the most vital step to the success of drug development is the selection of compounds with the optimal scaffold. For this purpose, a given pharmacophore model template is used to search for a hit among ligands that share a common pharmacological activity but have different scaffolds (Yang, 2010). This is known as scaffold hopping or lead hopping. It typically starts with a set of known active compounds and tries to discover structurally novel compounds by modifying the scaffold of the molecule (Böhm *et al.*, 2004). After accomplishment of an initial structure-activity relationship (SAR) study, a valid pharmacophore model is incorporated for scaffold hopping to deduce potential hits compounds (Sun *et al.*, 2012).

Fig. 3 Applications of pharmacophore modeling in drug design and discovery processes.

Pharmacophore-Based Virtual Screening

Pharmacophore-based virtual screening (PVS) is a subtype of ligand-based VS approach that utilizes the pharmacophoric feature perspectives in the identification of hit compounds (Balakumar *et al.*, 2017). In contrast to the structure-based VS such as docking (Bali *et al.*, 2012), the major advantage of PVS is that it is easy and less time consuming. A validated pharmacophore model serves as a template to search a large database of ligands to derive novel scaffolds bearing chemical features similar to the query pharmacophore. Handling of the conformational flexibility of database ligands and pharmacophore mapping are the two major steps in VS. The former considers multiple conformations for each ligand in the database while the latter verifies whether a query pharmacophore template is present in a given conformer or not. In case the query finds a hit, then both rigid and flexible fitting approaches will be employed. Rigid method of fitting considers the rigidity of conformations of ligands while calculating the best fit, whereas the flexible fitting permits conformational flexibility to the ligands by energy minimization, inter-feature distance and atom mapping parameters. Thus, the fit value will be assigned for each of the ligands and a higher value would represent the best mapping to the pharmacophore model and will result in the identification of highly active hit molecules.

Ligand Profiling

The structure-based pharmacophore modeling helps in the profiling of a set of ligands to predict the most likely targets for orphan bioactive ligands and anticipate adverse reactions, side effects (off-target effects) and proposing novel targets for drugs. Though, ligand-based pharmacophore modeling is also used for ligand profiling (Rognan, 2010), the application of structure-based pharmacophore modeling to profile ligands is usually preferred as it is fast, reliable and an efficient alternative to molecular docking while still representing specific ligand-protein interactions (Rella *et al.*, 2006).

Pose Filtering

The ligands that score highly as per the docking program scoring may not bind well in reality. Therefore, new methods are used where a docking program generates various ligand poses without considering the score given by the docking algorithm. Then, the poses are filtered with receptor-based pharmacophore searches. In pose filtering, the pharmacophore query can be placed into the binding pocket of the protein to filter potential ligand binding poses bearing all essential pharmacophore features to improve the probability of retrieving highly potent molecules for *in vitro* and *in vivo* experiments (Qing *et al.*, 2014).

Pharmacophore-Guided Fragment Design

It is generally easier to build up a fragment using smaller molecules than it is to reduce the size of a large one. This fragment-based approach is highly desirable because combining low molecular weight fragments offers the advantage of increased sampling of chemical space and the possibility of improved drug-like properties. Pharmacophore modeling can guide the designing of such a fragment that settles in an appropriate location in the binding site. When two or more pharmacologically active fragments are integrated, the chances of identifying the ligand pose seems to be greater. Thereby, we generate a group of fragments that may collectively yield pharmacologically active ligands. This application contributes to the lead molecule optimization stage wherein focussed hits are considered for refinement using the validated pharmacophore query (Miller and Roitberg, 2013).

Prediction of Pharmacological Activity

The 3D-QSAR based pharmacophore model has been used to predict the binding affinity of the test set ligands thereby predicting the pharmacological activity of those ligands well before an actual synthesis. Also, building pharmacophores of human ADME-related proteins (cytochrome enzymes) aids in the identification of various pharmacokinetic properties such as ADME (absorption, distribution, metabolism, excretion, and toxicity). Hence, pharmacophore modeling is very useful in the prediction of toxicity effects of drug-like molecules or even drugs (Rathee *et al.*, 2017).

Limitations of Pharmacophore Modeling Approaches

Unlike structure-based CADD approaches such as molecular docking, pharmacophore-based VS approach lacks reliable and good scoring metrics (Qing *et al.*, 2014). This significantly limits its applications in extending the scope of stand-alone predictions. Due to this missing element, even the ligands that may have all the requisite pharmacophoric features, may fail to exhibit *in vitro/in vivo* pharmacological activity. One of the reason for this observation is that pharmacophore modeling has inadequate consideration on the similarity with known potent ligands and overall compatibility with the target protein that complements the ligand. Hence, the structure of the identified hits may not complement the binding site of the target protein and may have other functional groups attached. Also, during a pharmacophore-based virtual screening from precomputed conformation databases, the database usually have only a limited number of low-energy conformations of the ligands. Therefore, successfully retrieval of active ligands may not be possible due to the missing conformations of the active ligand. Importantly, if a ligand has many rotatable bonds in its

structure, then it is very difficult to differentiate multiple rotations during the conformation generation process. As a rule of thumb, training set ligands are selected and thereby pharmacophore model is constructed. In such cases, it results in the generation of different pharmacophore models which upon VS yield different scaffolds claiming to be active hits. For example, in most of the cases, the kinase-inhibitor driven pharmacophore models result in the identification of novel scaffolds which may not be active for the specified kinase enzyme (Vancraenenbroeck *et al.*, 2014). Also, the success of pharmacophore modeling may be limited because the project is dealing with new compounds or targets that lack sufficient molecular information (Scior *et al.*, 2012).

Another challenging aspect of the pharmacophore-based virtual screening is the yield of a higher 'false positive' rate. This means that only a small percentage of the virtual hits are really bioactive (Yang, 2010). In simple words, the virtually identified hit ligands may not be pharmacologically 'active'. There are many factors associated with this limitation such as deficiency of required hypothesis, quality, the composition of the model, and the realistic behaviour of the ligand under biological environment. To overcome this major limitation of 'false positive' models, the following factors need to be considered (1) blending expert knowledge, (2) incorporating crucial target information, (3) rigorous validation, and (4) integrating other *in silico* approaches that offer a synergistic contribution to the success of the pharmacophore modeling.

Illustrative Examples

A couple of successful application of pharmacophore modeling have been discussed in this section to illustrate their potential significance in drug design and discovery of novel ligands.

Recently, a virtual screening of National Cancer Institute (NCI) database against the IdeR (a transcription factor of *Mycobacterium tuberculosis*) DNA binding domain was performed (Rohilla *et al.*, 2017). It was followed by *in vitro* inhibition studies using Electrophoretic Mobility Shift Assay (EMSA) and 9 lead compounds were identified and subjected to the structure-based similarity search to obtain four potent compounds. Further, lead optimization through the development of energy based pharmacophore and VS of ZINC database followed by molecular docking studies. These efforts yield one highly potent IdeR inhibitor. Authors developed five point energy based pharmacophore model using e-pharmacophore script under Schrodinger Package (Schrödinger, 2017). An energy based pharmacophore extracted and weighed interactions made by an inhibitor with the protein by using the descriptor information generated by the docking. A map of critical features contributing to the interaction between inhibitor and protein was generated using Glide module (Friesner *et al.*, 2004). LigPrep module of Schrodinger package was employed to generate energy minimized conformers and stereoisomers. All the resulted conformers were docked at the active site of the protein (PDB ID:1U8R (Wisedchaisri *et al.*, 2004)) by using Glide XP-precision mode. Based on the obtained XP descriptor file, the pharmacophore hypothesis was generated and was submitted to the e-pharmacophore script to yield a pharmacophore model. Thus, the created model consists of 5 features such as two hydrogen bond acceptors, two rings and one negative ionizable group. Based on the proximity with the key residues involved in DNA binding, each pharmacophoric points were carefully selected by these researchers. Further, screening of ZINC drug-like database (~13 million compounds) was carried out by using Phase (Dixon *et al.*, 2006). This resulted in ~110,000 molecules with a filter of 4 out of 5 molecular features to be matched. In this study, a five-point pharmacophore model provided valuable insight into the pharmacophoric features essential for IdeR inhibition. Also, the study led to the identification of one hit molecule exhibiting potent inhibition of IdeR.

Recently, we identified a hit molecule inhibiting the human kinesin spindle protein (KSP) through ligand- and structure-based *in silico* studies (Balakumar *et al.*, 2017). We have developed ligand-based pharmacophore models based on the available KSP inhibitors using BIOVIA-Discovery Studio software package (Dassault Systems, 2016). All the generated pharmacophore models were validated against *in house* test set ligands (54 compounds). Based on the validation parameters such as enrichment factor (E) and goodness of hit score, Hypo1 was selected as a valid model that consists of one ring aromatic (R), one positively ionizable (P), one hydrophobic (H), and two hydrogen bond acceptors (A₁ and A₂). The validated model (Hypo1) was then taken for database screening (Maybridge and ChemBridge) to yield hits, which were further filtered for their drug-likeness. To identify the ligand binding landscape, the potential hits retrieved from virtual database screening were docked to the active-site of the KSP (PDB: 4BXN Talapatra *et al.*, 2013) using CDocker (Wu *et al.*, 2003). The top-ranked hits obtained from molecular docking were used in molecular dynamics simulations to deduce the ligand binding affinity. This study identified MB-41570 as an inhibitor of KSP.

Conclusion and Future Perspectives

Unequivocally, the pharmacophore modeling approaches still serve as one of the most widely used and successful tools in CADD projects and medicinal chemistry. Though a considerable development in the pharmacophore modeling has happened, further improvements in pharmacophore modeling techniques are required. To enhance its success rate in real-time experiments, several aspects such as developing accurate, optimized/predictive models, better handling of ligand flexibility and efficient algorithms for ligand alignments must be considered. There could be a positive contribution in the form of the target binding-site information that can assist in developing the structure-based models more efficiently. Better algorithms can be developed in the area of fragment-based drug design involving pharmacophore fingerprint-based similarity search and generation of 3D pharmacophore queries. Another potential scope of pharmacophore modeling is the development of small molecule inhibitors of protein-protein interactions (PPIs), wherein the pharmacophoric queries will be generated by encoding the crucial interactions at the PPI interface. Hence, there are multiple new horizons to be explored through the application of pharmacophore modeling techniques in designing therapeutics.

Introduction

In the drug discovery process, finding new leads is an expensive and time-consuming process. The development of the combinatorial chemistry and high-throughput screening (HTS) technologies in the early 1990s has allowed enormous libraries of compounds to be synthesized and screened in a short period of time. However, many of the identified have failed in the lead optimization process due to their poor pharmacokinetic properties. Therefore, it was necessary to develop alternative strategies that might help to select appropriate series of compounds and eliminate unsuitable structures and thus could save a significant amount of time and resources. For this purpose, computational techniques such as virtual screening (VS) can be applied as an important step in the early stage of the drug discovery process (Lavecchia and Di Giovanni, 2013). While HTS aims to experimentally test a large number of compounds in the most efficient manner, VS attempts to rationalize those compounds to reduce the number for experimental testing as much as possible (Ripphausen, *et al.*, 2011). Furthermore, the compounds evaluated do not necessarily exist, or in other words, any molecule of compound theoretically can be evaluated by VS (Lavecchia and Di Giovanni, 2013). In the VS process, a large library of compounds is filtered and reduced by a computational algorithm based on their predictive binding mode with the target, which will then be tested experimentally (Tanrikulu, *et al.*, 2013). Fig. 1 shows the differences between DBVS and HTS. Unlike HTS, DBVS allows us to test only compounds with high scoring, hence lowering the cost of hits discovery (Shoichet *et al.*, 2002; Villoutreix *et al.*, 2000). VS can be classified into two categories, namely ligand-based virtual screening (LBVS) and structure-based virtual screening (SBVS). LBVS involves the utilization of structural data from a series of known active compounds to find candidates for experimental testing. It includes several methods such as similarity searching, quantitative structure relationships (QSAR), and pharmacophore fitting. Whereas SBVS, or docking-based virtual screening (DBVS), employs the three-dimensional (3D) structure of the target macromolecule that is obtained experimentally either through X-ray crystallography or NMR or computationally through homology modeling. The candidate molecules were docked to the target macromolecule to investigate the binding mode and rank them based on their predicted binding affinity (Lavecchia and Di Giovanni, 2013).

Both LBVS and SBVS approaches are powerful technologies that promise to accelerate the pace and reduce the cost of discovering new drugs, which can be applied to VS for lead identification and optimization (Villoutreix *et al.*, 2000; Lengauer *et al.*, 2004; Vyas *et al.*, 2008; Xu and Agrafiotis, 2002).

Fig. 1 DBVS selects hits compound based on the scoring function, while all compounds in HTS are being tested.

Molecular docking is a computational tool of structure-based drug design to predict protein–ligand interaction geometries and binding affinities (Cosconati *et al.*, 2010; Vyas *et al.*, 2008). In DBVS, compounds in the database are scored and ranked based on their steric and electrostatic interactions with the target site and the best compounds are tested further with biochemical assays (Singh *et al.*, 2006). The search algorithm should generate an optimum number of conformations for the ligands and of poses that should include the experimentally determined binding mode. The scoring functions commonly used in docking are force-field based, empirical-based, and knowledge-based. For this reason, there are many considerations in choosing the best compound based on the ranking in DBVS result. Several scoring functions have been developed during the past few years (Breda *et al.*, 2008; Friesner *et al.*, 2004; Jain, 2006; Kastiris and Bonvin, 2010; Kroemer, 2003; Shoichet *et al.*, 2002). There are numerous programs available for DBVS, such as Autodock (Morris *et al.*, 1996), GOLD (Jones *et al.*, 1997), DOCK (Ewing *et al.*, 2001), FlexX (Rarey *et al.*, 1996), Glide (Halgren *et al.*, 2004), LigPlot (Wallace *et al.*, 1995), and FRED (McGann, 2011). Among these programs, Autodock is the most used program for docking in scientific journals and freely available for academic work. There are some important factors to be considered in choosing docking software, including the capability for iterative refinement of docking parameter/protocol based on new results, the adaptability to additional scoring functions, pre- and/or post-docking filters, design components and results of validation studies, user learning curve, customer supports, cost, speed, user interface, input/output structural file formats, code availability, and upgrading possibility (Ghosh *et al.*, 2006).

Databases for Virtual Screening

Databases of small molecules are required for all VS projects. There are millions of compounds from structural databases of more than 32 providers gathered and stored in a single chemical database. By using the “Lipinski rule of five,” around 2.1 million of compounds are categorized as “drug-like,” and more than 1 million are lead like (Monge *et al.*, 2006).

However, the drug-likeness of chemicals from the database should be calculated, to avoid a clinical candidate that is too big, resulting in bad solubility and/or permeability (Verheij, 2006). When selecting compounds for screening, traditional “druglike” property cut-off values (e.g., Lipinski’s “rule of five”: MW < 500, LogP < 5, hydrogen acceptor < 10, and hydrogen donor < 5) (Lipinski *et al.*, 2001; Verheij, 2006) might cause problems later during the lead development stage (Verheij, 2006).

Recently, many collections of chemical library databases are available on the web. Some of the commonly used small molecule databases in VS are ZINC (free database of 3.3 million commercially available compounds), the Available Chemicals Directory (ACD; 4 million entries, not free), National Cancer Institute compound database (NCI; free database of 400,000 entries), and MDDR (MDL; Drug Data Report > 147,000 entries). Besides, a chemical library containing synthetic single compounds, combinatorial compounds, and natural product compounds (Hong, 2011; Rollinger *et al.*, 2006), and marketed drugs library (Hong, 2011; Lopez-Perez *et al.*, 2007; Quinn *et al.*, 2008) are also available. Lopez-Perez and colleagues developed NAPROC13 (Lopez-Perez *et al.*, 2007) containing ¹³C spectral information of over 6000 natural compounds. This database allows us to identify the known compounds present in the crude extracts and provides insight into the structural elucidation of unknown compounds. Moreover, Dunkel *et al.* (2006) developed a SuperNatural database that contains 3D structures and conformers of 45,917 natural compounds and about 300 natural compounds that are similar to active ingredients of drugs. It is known that 8% (3600) of this database is identical to the marketed drugs.

Another database of natural compounds is NADI (Natural Drug Discovery), which was developed by Wahab *et al.* (2009). It is a database of Malaysian medicinal plants that aimed to be a one-stop center for in silico drug discovery from natural products. It provides structural information of around 3000 different compounds, complete with the botanical sources of plants species that could be used in VS. Compounds in the NADI database can be searched based on the name, plants, structure formula, molecular weight, substructure, and SMILES code. In addition, around 40 monographs of Malaysian herbal medicine were available. They contain an integrated information regarding the description of plants, bioactivity, efficacy and usefulness, diseases target, and references. NADI is also enriched with the target protein database, composed of 645 validated drug targets useful for rapid VS. This database was successfully used to obtain lead compounds for neuraminidase inhibitors. Ikram *et al.* (2015) screened 3000 compounds from the NADI database using AutoDock against neuraminidase, a drug target of the influenza virus. The top 100 compounds were then categorized into five plants. Interestingly, some fractions and pure compounds from the five plants showed good inhibitory activity against the neuraminidase of the influenza virus (Muchtaridi *et al.*, 2014).

Case Study

In this case study, we will do a DBVS of compounds from National Cancer Institute (NCI) database to find the potential hits as *Mycobacterium tuberculosis* (Mtb) thymidylate kinase (TMPK) inhibitor. TMPK is one of the validated drug targets for Mtb. NCI provides a diversity set consisting of about 2000 compounds representing a 140,000-chemical space. The NCI diversity set is a good choice of database for virtual screening exercise because NCI also provides real compounds for further experimental testing. The compounds, when available, can be requested for free (see “Relevant Websites section”). The procedure to obtain the vialled samples is explained in this web link provided in: “Relevant Websites section”. A crystal structure of Mtb TMPK in complex with its

Fig. 2 Mtb TMPK in complex with TMP analog. Protein surface represents an increasing level of hydrophobicity (blue → white → brown colors). The ligand is visualized in green sticks. A green sphere, a magnesium ion, is located near the ligand. This figure is generated from PDB ID 1MRS using Biovia Discovery Studio Visualizer.

inhibitor with PDB ID 1MRS is used in this case study (**Fig. 2**). The ligand is thymidylate monophosphate (TMP) analog, possessed a nanomolar inhibition towards TMPK (Haouz *et al.*, 2003).

Programs that used in this case study are AutoDock 4.2, AutoDockTools (ADT), Raccoon, and Biovia Discovery Studio Visualizer (BDSV). ADT is a GUI of AutoDock which can be used to set up input files and docking parameters. AutoDock 4.2 and ADT is available in Windows, Linux, and Mac OS. They can be downloaded from websites provided in “Relevant Websites section” and “Relevant Websites section,” respectively. BDSV is also a freeware that can be obtained through website provided in “Relevant Websites section.” Moreover, automated DBVS of thousands of ligands will be executed by a bash script. In this case study, we choose one of the most popular and user-friendly Linux OS, that is, Ubuntu 16.04. Linux is a native environment of most of the computational chemistry program. Therefore, to have experience in operating DBVS under Linux should be beneficial to the beginner.

In general, DBVS using AutoDock consists of eight main steps: Ligand processing, receptor preparation, grid parameter setup, affinity maps calculation, protocol validation, docking parameter setup, virtual screening execution, and lastly screening result analysis.

Preparation of Ligand From Database

The database of ligands is usually compiled in a single “MOL2” file, not the individual file. For this reason, a tool called Raccoon (see “Relevant Websites section”) can be used to prepare the PDBQT format for each of ligand, a native filetype of AutoDock. The Graphical User Interface of Raccoon is presented in **Fig. 3**.

If all the ligands are wrapped in a single MOL2 file, then we must click ‘Utilities → Split a MOL2 → Open’. All the spliced MOL2 files will be generated accordingly in the same directory with its parent file. Furthermore, an automatic process of converting 2000 ligands from MOL2 format into PDBQT is accomplished by using ‘[+] Add ligands’ button. It is noted that not all ligands will be successfully converted into the PDBQT format due to some reasons, for example, a number of torsions, atom-type parameter. Therefore, in this case study, a hassle-free PDBQT-formatted NCI Diversity Set II, namely “NCI-Diversity-AutoDock-0.2.tar.gz,” can be directly downloaded from website provided in “Relevant Websites section.” This file consists of 1541 ligands, a few hundred less than the original database. All ligands with AutoDock-unsupported atom type (such as selenium) and a large number of active torsions have been discarded from the list. For the sake of accuracy, AutoDock has a default maximum rotatable bonds of 32.

Preparation of Receptor and Control Ligand

- (1) The receptor preparation will be done by ADT, which can be opened by typing ‘adt’ in the Linux terminal. The interface of ADT is presented in **Fig. 4**.
- (2) A working directory of ‘/home/USER/vs’ in ‘File → Preferences → Set → Startup Directory’ should be determined. This step will ensure all the modified files will be placed in one working directory.

Fig. 3 The interface of Raccoon.

- (3) The PDB file of TMPK complex can be directly downloaded using ADT by clicking 'File → Import → Fetch from Web → 1MRS'.
- (4) AutoDock uses implicit water solvent model. Therefore, in most cases, all of the crystal water should be removed by using 'Edit → Delete Water'.
- (5) Most of the crystal structures in PDB lack hydrogens. All the hydrogen atoms should be added to the structure by using 'Edit → Hydrogens → Add → All Hydrogens → noBondOrder'. Furthermore, the hydrogenated PDB is saved using 'File → Save → Write PDB → 1MRS_H.pdb'.
- (6) The ligand and receptor are separated into an individual file using Linux terminal. In the terminal, go to the working directory by typing:

```
$ cd ~/vs/source
```

 In PDB 1MRS, the residue name for the ligand is "5HU". Therefore, the ligand can be extracted from the complex using grep command:

```
$ grep "5HU" 1MRS_H.pdb > 1MRS_ligand.pdb
```

 Whereas the receptor can be extracted by typing:

```
$ grep "ATOM" 1MRS_H.pdb > 1MRS_receptor.pdb
```

 As mentioned before (Fig. 2), a magnesium cofactor is located near the ligand, and hence might have an important role in the active site. This ion, with residue name "Mg," can be added to the receptor file by typing:

```
$ grep "Mg" 1MRS_H.pdb >> 1MRS_receptor.pdb
```

please note the use of ">>" instead of ">"
">>" means to add a new line(s) to the current file, while ">" means to replace the whole text with the new one. In this step, we want to add Mg as part of the receptor.
- (7) Finally, the receptor and control ligand is required to be converted into PDBQT format using ADT. Here are a few steps to be done:
 - Clean up the molecule windows by using 'Edit → Delete → Delete All Molecules'.
 - In ADT4.2 widget, select 'Ligand → Input → Open' and choose 'PDB files' in 'Files of type' menu. Select '1MRS_ligand.pdb' then click 'Open'. Save the ligand in PDBQT format by select 'Ligand → Output → Save As PDBQT', name it as '1MRS_ligand.pdbqt' then click 'Save'.
 - In ADT4.2 widget, select 'Grid → Macromolecule → Open', and choose 'all files' option in the 'Files of type'. Select 1MRS_receptor.pdb and click 'Open'. ADT will read its coordinates, add charges, merge nonpolar hydrogens, and assign appropriate atom types. Click 'OK' to accept the changes. A window will pop up to write the PDBQT file. Click 'Save' to write the file namely '1MRS_receptor.pdbqt'.
 - By default, the atomic charge of Mg will be set to 0. This value can be modified later manually using any text editor in Linux (such as gedit, nano, or geany) before docking.
 - Please note to keep the receptor and control ligand loaded in the molecule window to continue with the next step.

Fig. 4 Interface of AutoDockTools.

Grid Parameter Setup and Affinity Maps Calculation

In this step, we will calculate the affinity maps for each atom types of the ligand. Before that, we should determine the coordinate and the size of the ligand binding site, represented by a grid box, which is used as a target for VS.

- (1) In ADT4.2 widget, specify the atom types included in the loaded 1MRS_ligand.pdbqt by using 'Grid → Set Map Types → Choose Ligand → Select Ligand'.
- (2) Define the center of searching space based on the position of control ligand by using 'Grid → Grid Box → Center → Center on Ligand'. The size of grid box can be adjusted manually to cover the interacting residues (Fig. 5). Save the setting by clicking 'File → Close Saving Current'.
- (3) Save the control ligand's grid parameter file as "control.gpf" using 'Grid → Output → Save GPF'. However, this gpf file is not the one that will be calculated using AutoGrid.
- (4) It is noted that in a virtual screening setting, the size of grid box should consider the size of the compound in the database used for SBVS. This can be performed by using a python script included in the Utilities24 folder, that is, prepare_gpf4.py. This script can also be used to extract all the atom types consisted of the database. Here, "control.gpf" will be used as a reference file to create a global gpf file for the whole virtual screening process.

```
$ cd ~/vs/source
$ pythonsh ~/Utilities24/prepare_gpf4.py -r 1MRS_receptor.pdbqt
-d ../ligand -i control.gpf -o vs.gpf -v
```

This command will generate a new gpf file covering all atom types in the database and adjusting the size of grid box based on the size of all included compound without changing the center of the grid box. It is noted that several ligands have a larger size than the original box size. In this case, it is important to consider whether to follow the new size, which increases the searching space or to stick with the previous size (if the majority of ligands covered). *Take note that the symbol "\ " means to*

Fig. 5. Grid box setting in AutoDockTools.

continue with the next line. The symbol “\” itself does not need to be typed.

- (5) Calculate the affinity maps of all atom types in the database by using AutoGrid.

```
$ autogrid4 -p vs.gpf -l vs.glg
```

Docking Parameter Setup

In general, there is no good-for-all docking parameter setting. It depends mostly on the searching problem, which is represented by the size of searching space and ligand's degree of freedom. Before preparing the docking parameter for VS, we must do one for the control ligand, which can be used as a reference setting later. AutoDock stores the docking parameter in a DPF file, which can be prepared as follows:

- (1) Select the macromolecule by clicking 'Docking → Macromolecule → Set Rigid Filename' in ADT4.2 widget and choose the '1MRS_receptor.pdbqt'.
- (2) Select the ligand by using 'Docking → Ligand → Choose → 1MRS_ligand.pdbqt'.
- (3) Select the genetic algorithm as the docking method by using 'Docking → Search Parameters → Genetic Algorithm Parameters'. Modify the number of GA runs and a maximum number of evaluation to 100 and 5,000,000, respectively.
- (4) If needed, a more advanced parameter setting can be modified through this menu in the ADT4.2 widget: 'Docking → Docking Parameters'.
- (5) Save the docking parameter file as "control.dpf" by using 'Docking → Output → Lamarckian GA'.

Control Docking or Validation the Docking Method

We may test our docking parameter by control docking method. It is basically a redocking of the cocrystallized ligand from the random state back into its receptor. When the docking is able to reproduce the experimental conformation and position, its

Fig. 6 The result of control docking of ligand (green colored stick) as compared to its crystal pose (gray colored stick). A green sphere is a magnesium ion located at the binding site.

parameter is considered to be used for VS. It is known that the acceptable root-mean-square-deviation (RMSD) value between the docked ligand and crystal ligand is below 2 Å.

Please note that a magnesium ion existed in the receptor file. By default, its charge was set to 0, which is not right. Before docking, we should manually edit the '1MRS_receptor.pdbqt' using any text editor by changing the atomic charge of Mg. In this session, we changed its charge from 0 to 1 (not 2) to mimic the solvent effect around the magnesium ion.

- (1) In the Linux terminal, type:

```
$ cd ~/vs/source
```

```
$ autodock4 -p control.dpf -l control.dlg
```

We can use 'tail -f control.dlg' to monitor the progress of docking process.

- (2) Analyze the DLG file by using any text editor, especially under 'Clustering Histogram' section. The lowest energy docking pose is mentioned after the RMSD Table.

RMSD TABLE						
Rank	Sub-Rank	Run	Binding Energy	Cluster RMSD	Reference RMSD	Grep Pattern
1	1	1	-9.28	0.00	0.97	RANKING
1	2	5	-8.07	1.02	1.08	RANKING
1	3	3	-8.06	0.93	1.31	RANKING
1	4	4	-7.96	1.77	1.70	RANKING

A successful control docking was indicated by the small RMSD value between docked pose and that of reference (0.97 Å) (Fig. 6). It is noted that if we did not change the atomic charge of Mg, the docking result would be worse than this. A separate docking was conducted using the Mg charge of 0, which resulted in an RMSD of 4 Å, indicating a nonreliable docking parameter.

Virtual Screening

Fig. 7 shows that our VS working directory consists of three subfolders, namely ligand, docking, and source. All ligand PDBQT are stored in ligand folder. Using a reference grid and docking parameter files, receptor PDBQT and affinity maps in the source folder, we will generate a working directory for each ligand in docking folder. Each ligand's folder will consist of PDBQT files of ligand and receptor, affinity maps, and docking parameter file. Moreover, there are Python scripts that are very useful in helping the virtual screening process, located in the folder "Utilities24" of ADT installation (by default, it is located in '/home/USER/mgltools*/MGLToolsPkgs/AutoDockTools/Utilities24'. In this practical session, the whole directory of Utilities24 has been copied to the home directory. Hence it can be accessed at '~ /Utilities24'. (note: "~" means /home/USER/ directory)

A map of working directories is visualized in Fig. 7, particularly to organize the virtual screening process in this exercise.

Bash script provided in this article might not the smartest way to do DBVS. However, it is noted that this article is provided to the beginner, especially those who want to do DBVS using their personal computer, not on the multinodes rack server. This process can be done by executing a bash script as follows: (If you are still not familiar with a bash script, please note to press "enter" at the end of each line)

Fig. 7 Structure of directory in DBVS.

To type in the terminal	Explanation
<code>\$ cd ~/vs/docking/</code>	Enter the working directory
<code>\$ for i in \$(ls ../ligand/)</code>	For each "i" in the result of "ls" of ligand directory
<code>do echo \$i</code>	Display list of "i"
<code>j=\$(basename \$i .pdbqt)</code>	Declare "j" from the removal of ".pdbqt" from "i"
<code>echo \$j</code>	Display the list of "j"
<code>mkdir \$j</code>	Create the directory of "j"
<code>cp ../ligand/\$i \$j</code>	Copy the ligand.pdbqt to its respective folder
<code>done</code>	Done, iterate back until all "i" finished

At this point, each ligand's working directory consists of ligand.pdbqt. Since a docking process needs a receptor file, affinity maps, and docking parameter file, then the following script should be executed:

To type in the terminal	Explanation
<code>\$ cd ~/vs/docking/</code>	Enter the working directory
<code>\$ for i in \$(ls)</code>	For each "i" in the result of "ls"
<code>do echo \$i</code>	Display list of "i"
<code>cd \$i</code>	Enter the directory of "i"
<code>ln -s ../source/1MRS_receptor.pdbqt.</code>	Create a link to receptor file
<code>ln -s ../source/*map*.</code>	Create a link to map files
<code>pythonsh ~/Utilities24/prepare_dpf42.py</code>	Prepare a docking parameter file for each ligand based on the reference file (control docking)
<code>-l \$i.pdbqt -r 1MRS_receptor.pdbqt</code>	
<code>-i ../source/control.dpf -v</code>	
<code>cd..</code>	Exit the directory "i"
<code>done</code>	Done, iterate back until all "i" finished

The script of "prepare_dpf42.py" will use the parameters in control docking "dpf" as the reference to generate a new "dpf" file for each ligand docking.

Finally, a run of VS will be executed. This script will enter each ligand's directory and do docking. After finishing with one docking, this script tells to go back to the parent directory and continue with the next ligand.

<i>To type in the terminal</i>	<i>Explanation</i>
\$ cd ~/vs/docking/	Enter the working directory
\$ for i in \$(ls)	For each "i" in the result of "ls"
do echo \$i	Display list of "i"
cd \$i	Enter the directory of "i"
autodock4 -p *.dpf -l \$i.dlg	Execute docking of ligand "i"
cd ..	Exit the directory of "i"
done	Done, iterate back until all "i" finished

Analyze the Virtual Screening Results

Summarize the VS results by using a Python script from AutoDockTools, namely summarize_results4.py, which located in the "Utilities24" folder.

```
$ cd ~/vs/docking
$ for i in $(ls)
do echo $i
pythonsh ~/Utilities24/summarize_results4.py -d $i -t 2.0 -B -k -e
-r 1MRS_receptor.pdbqt -o ../vs_summary.txt -a -v > > ../vs.log
done
```

Here is the detail of the options of summarize_results4.py:

- d Set the directory name that represented the docking folder of each ligand
- t RMSD tolerance between poses to cluster the docking result
- B to result in only the best docking and the largest cluster only (not all poses will be printed)
- k to report the number of hydrogen bond and its energy
- e to break down the binding energy into electrostatic, van der Waals, hydrogen bond, and desolvation energies
- r to identify the receptor file
- o output filename
- a append to output filename. This is ideal for analyzing VS results since they will be appended to a single file
- v verbose output

The resulted "vs_summary.txt" is a comma-separated value (CSV) file that can be imported to a popular worksheet program such as Microsoft Excel (as XLS file). Here is an example of an XLS file, a popular worksheet format, derived from the VS summary file.

Ligand	Lowest energy	No. of H-bond	Electrostatic energy	H-bond energy	Van der Waals energy	Desolvation energy	No. of atoms	No. of torsions	Ligand efficiency
1	-11.42	5	-4.94	-2.35	-10.34	4.82	25	5	-0.54
2	-8.22	5	-0.66	-2.17	-10.05	3.77	23	4	-0.41
3	-7.32	4	-0.72	-1.81	-8.71	3.33	19	3	-0.46
4	-11.46	3	-5.34	-2.56	-11.28	5.45	28	7	-0.50
5	-11.17	3	-4.60	-1.54	-12.48	4.98	29	6	-0.41
Control	-10.82	6	-4.17	-2.75	-10.89	5.00	25	7	-0.49

In principle, the calculated binding energy represents the predicted affinity of ligand to the receptor. However, many DBVS efforts resulted in a false positive result if the selection of active hits was only based on the binding energy. Docking score is not the absolute binding energy, hence we should consider the other aspects in filtering the screening result. For example, the TMPK's binding site is composed of many charged residues. Therefore, electrostatic interactions between the ligand and receptor are expected, including hydrogen bond formation. The screening result then can be sorted based on its electrostatic or hydrogen bond energy. The script of "summarize_results4.py" provides the breakdown of total binding energy into its components, such as a number of the hydrogen bond, intermolecular energy, and desolvation energy. Ligand efficiency also can be used to predict the ligand potency in binding to the receptor. It is a ratio between the binding energy and number of the atom. A higher value of ligand efficiency indicates a major contribution of a ligand's atoms to the interaction with the binding site. For this reason, the result of VS can be sorted based on many parameters, not only the binding energy.

Fig. 8 Molecular interaction of (a) the best ligand (blue sticks) and (b) the ligand with similar pose with the positive control (gray sticks).

Besides the energy value, the selection of the best ligand can be assessed based on the intermolecular interaction with the receptor. For this purpose, the best conformation of each ligand can be prepared using the following script:

To type in the terminal	Explanation
\$ cd ~/vs/docking/	Enter the working directory
\$ for i in \$(ls)	For each "i" in the result of "ls"
do echo \$i	Display list of "i"
cd \$i	Enter the directory of "i"
pythonsh	Extract the ligand's conformation with the lowest energy, resulted in a
~/Utilities24/write_lowest_energy_ligand.py	"i_BE.pdbqt" file
-f \$i.dlg -v	
pythonsh ~/Utilities24/pdbqt_to_pdb.py	Convert the pdbqt format of "i_BE.pdbqt" into pdb file
-f *BE.pdbqt	
cd ..	Exit the directory of "i"
Done	Done, iterate back until all "i" finished

Then, we collect all the best conformation of ligands into a new folder called "best_pose."

To type in the terminal	Explanation
\$ cd ~/vs/docking/	Enter the working directory
\$ mkdir ../best_pose	Create a new directory of "best_pose" in the upper level
\$ cp */*BE.pdb ../best_pose	Copy all of the best poses of ligands into the new directory

Furthermore, we can combine the information derived from the table of results with the visual assessment. The PDB file resulting from the step above can be imported directly to BDSV (or any visualizer program). **Fig. 8(a)** shows that ligands with the best docking score sometimes do not form similar interaction with the control ligand. Near the magnesium ion, there are three positively charged residues, i.e., K13, R95, R160. While the control ligand formed a hydrogen bond, the best ligand formed Pi-cation interactions. Another ligand with moderate binding energy could form similar pose and interaction (**Fig. 8(b)**). The aromatic ring of this ligand perfectly fit the position of control ligand. Therefore, this ligand is also worth testing in further experiments.

Conclusion

The advances of docking software and computer hardware technology, and the availability of structure databases and experimental data, are strong reasons for integrating DBVS into each drug discovery project. DBVS is useful for narrowing hits candidates before in vitro experiment. However, in-depth analysis of DBVS result would enhance the successful rate of prediction. Deep understanding of the protein target should be useful to pick important parameters in selecting the best ligands for further testing, besides the docking binding energy. The protocol explained in this article is an introduction of how DBVS can be done using a personal

desktop computer, which is usually found in the office or laboratory. A tutorial of DBVS in a Linux environment can be also a good start to further advance VS procedures, which mostly run in Linux.

Molecular Phylogenetics

Michael A Charleston, University of Tasmania, Hobart, TAS, Australia

Introduction

This Section begins with a basic motivation as to why (molecular) phylogenetics is important, and then introduces some of the relevant terminology. Section “Overview” continues with an overview of the phylogenetic inference process: From sequence alignment to constructing or estimating trees. Section “Common Assumptions in Molecular Phylogenetics” then explores the assumptions that are made in the name of phylogenetic inference: To do with the alignment itself, assumptions about independence, the direction of time, the nature of speciation, and similar. The last section discusses methods of finding the best tree, followed by a brief discussion on Bayesian methods and MCMC before some final comments on what (else) can possibly go wrong with molecular phylogenetic inference.

Motivation

Phylogenetic analysis is strongly motivated by our need to understand the relationships among species that have evolved from common ancestors. As – at least in theory – *everything living* has arisen from a common ancestor around 3.5–4.4 billion years ago, it is not beyond our imagination to conceive of a single over-arching “Tree of life” that describes the relationships among all extant and extinct species, from viruses to plesiosaurs. Understanding such relationships, both in terms of patterns of speciation and the times at which they occurred, is key to our ability to compare species within a framework that makes statistical *sense*. Without frameworks like phylogenetic trees (or even networks – see later) it is not possible to properly account for the shared history of species when comparing their characteristics.

But estimating phylogenetic history is hard. There are a number of reasons for this, but perhaps the most obvious is that we cannot travel backward in time to check whether what we have attempted to uncover is in fact correct. Another difficulty is that the number of phylogenetic trees is enormous. It’s been long known (since at least 1870 ([Schröder, 1870](#)); more elegantly in ([Cavalli-Sforza and Edwards, 1967](#))) that the number of possible trees for n species grows at a frightening rate: so much so that for even modest numbers of species, around 100, there are more than 3×10^{184} trees – many, many more than the estimated number (something around 10^{82}) of particles in the universe! So not only is it hard to check whether a tree is “right” (leaving aside for a moment the potential issues of assuming that evolution is tree-like), but it’s also computationally intractable to search through the space of all possible trees for the best one.

Language of Phylogenetic Inference

Phylogenetics is rich in terminology, having gained it from mathematics, biology, and computer science, and it can be confusing. It is worth defining the terms we will be relying on at this point ([Box 1](#)).

Box 1: Terminology

Analogy: a feature of related species that is similar, but is not derived from their common ancestor (c.f., homology).

Branch: also known as an edge in a phylogenetic tree, it is equivalent to a split of the leaf nodes (taxa) into two subsets. The “same” branches can therefore occur in multiple trees, so long as they separate the taxa into the same subsets.

Character, character state: we distinguish the character, which is the particular feature such as “nucleotide” at a given site, with its state, which in this case would be A, C, G, or T.

Clade: a monophyletic group.

Graph: a collection of nodes, and pairs of nodes called edges.

Homologous: of a character, feature or site that is shared and derived from a common ancestor (c.f., analogy).

Leaf (tip) a node of a tree that is adjacent to exactly one branch (or edge); corresponding to extant taxa.

Likelihood: a method by which the probability of a given observation can be calculated, conditional on an assumed probabilistic model.

Locus; plural loci: a site or sequence within a molecular sequence.

MRCA most recent common ancestor of a set S of taxa: The node in a rooted phylogeny that is closest to the leaves, that is ancestral to all the taxa in S .

Monophyletic, monophyly: a taxon set S in a tree is monophyletic if it contains all the descendants of the most recent common ancestor of S .

Network: in phylogenetics, a graph that contains multiple paths between at least some pairs of nodes, either representing a hypothesized history of hybridization and/or horizontal gene transfer, or support for conflicting splits of the taxa.

Paraphyletic, paraphyly: a taxon set S in a tree is paraphyletic if it contains most, but not all, of the descendants of the MRCA of S .

Phylogeny: also called a phylogenetic tree, a tree whose nodes represent taxa or operational taxonomic units (OTUs) and whose branches correspond to evolutionary lineages.

Root: a node of a phylogenetic tree that is specially designated as the common ancestor of all the other nodes.
 Sequence: in the context of molecular phylogenetics, sequence means linear array of biological characters, e.g., nucleotides.
 Site: a position in a molecular sequence, e.g., the 10th nucleotide in the gene coding for *gag* protein.
 Split: a partition of the taxon set of interest into two subsets, with empty intersection and no taxa missing. Equivalent to a branch.
 Taxon; plural taxa: a phylogenetically distinct biological type, e.g., species or genus.
 Tip: a node corresponding to an extant taxon.
 Tree: a graph in which each pair of nodes has exactly one path connecting them.

Overview

Molecular phylogenetics is concerned with the estimation of the evolutionary relationships of species or other types of taxa that we can observe today. It is a computationally and statistically challenging task, but it is central to enabling comparison of species within an appropriate statistical framework.

Molecular phylogenetics is a routine pursuit in modern biology, and while it is broadly a simple process, the details are not inconsequential. The general process is as follows: (1) Obtain a set of comparable molecular sequences across the range of taxa of interest, (2) align those sequences so individual positions in each sequence correspond to each other, (3) build or search for a tree or set of trees with methods as briefly described herein, (4) test the tree(s) for their correctness, and generally (5) use the tree(s) to answer a question about the species, e.g., when was the divergence into the major clades of birds. It is possible to skip step (2) if re-analysing an existing data set.

Data

Beginning the whole inference process is the creation and curation of suitable data.

For molecular phylogenetics, the data are sets of homologous sequences, e.g., those of particular genes, represented as strings of adenine (A), guanine (G), cytosine (C) and thymine (T) for DNA, or A, C, G, uracil (U) for RNA sequences; occasionally too these sequences are transformed into simpler encoding as purines (A, G) and pyrimidines (C, T/U). Of course it is also possible to use amino acids as characters in such sequences, or even the 64 codons that encode them (usually removing the 3 “stop” codons from consideration within a protein encoding gene).

Homologous means that the sequences correspond to each other across species in the obvious desirable way: They branched and diversified from each other at the speciation events that we’re trying to recover. Sequences that are paralogous, that is, they don’t have the same evolutionary history as the species in which they reside, are more problematic for phylogenetic analysis because correctly recovering the evolutionary relationships among the sequences does not directly give you the relationships among the species.

Usually sequences that are likely to show some evolutionary “signal” are chosen for phylogenetic inference: those that have some constraints so they do not evolve too quickly as to appear random with respect to each other.

Depending on the overall age of the set of taxa of interest, slower or faster regions in the homologous sequences are chosen. For example to estimate the phylogenetic relationships among a group of viruses over 100 years, the *env* gene might be used; for investigating deep historical relationships among archaea, bacteria and eukaryota, much more conserved genetic regions must be chosen such as DNA polymerases.

Aligning the Sequences

The sequences must be aligned, that is, arranged relative to each other with the possible insertion of gaps at different places, such that for each sequence, the characters (e.g., nucleotides, amino acids, purines/pyrimidines etc) at position *i* have the same evolutionary history as each other. In this sense the positions, which are generally called *sites*, are also hoped to be homologous. [Fig. 1](#) shows how some toy DNA sequences might evolve on a tree, showing homologous sites, insertion/deletion events, and illustrating how reconstructing the branching order might be tricky. Maybe reword here.

Alignment would be trivially easy if the only mutations that could occur were changes of state, e.g., from A to T, but sequences evolve in other ways also. In the context of sequence alignment the main other mode by which sequences can change is via deletion of sections of sequence, or insertion of new sections. Faced with two sequences that have been optimally aligned, in which there is a section in one that is “extra” (see [Fig. 1](#) and the table below), it is not possible to determine whether that section was inserted in one sequence, or deleted from the other one. For this reason such regions are referred to also as “indels” and the events are indel (insertion/deletion) events.

To find the optimal alignment of just two sequences is relatively straightforward: first, choose a costing function that accounts for similarities and differences between aligned sites in the two sequences, as well as gaps in either caused by insertion or deletion events during their evolution, and then use dynamic programming to search through the complete space of possible alignments in an efficient way ([Waterman et al., 1991](#)). Costing the match or mismatch of characters like nucleotides, amino acids or codons is usually done by performing log-odds analyses of pairs of curated sequences that are agreed to be correctly aligned, at various levels of difference (e.g., BLOSUM ([Henikoff and Henikoff, 1992](#)), [Fig. 2](#); PAM ([Dayhoff et al., 1978](#)); JTT, ([Jones et al., 1992](#)) etc.). The match and mismatch scores are often rounded to integer values for computational efficiency, which is generally a “safe” assumption given that the log-odds are themselves approximations, derived from hand-picked and often hand-aligned data.

	A	4			
	G	1	5		
	C	0	-1	4	
Score =	T	1	-1	0	3
	gap	-7	-7	-7	-7
	A	G	C	T	

Fig. 3 Example cost matrices for nucleotide alignment. These scores are illustrative only.

In Alignment 1 a gap has been inserted at position 3 for taxa g and h, with the remaining sequences having a G at that position; the other sites all show multiple character states. Alignment 2 has a constant site at position 5, but at considerable expense elsewhere in the alignment as more gaps have been inserted than are biologically realistic. (Note that if Alignment 2 were optimal for some alignment program, the gap cost is set far too low in comparison to that for a mismatch between character states.) In general we hope to obtain alignments that show a degree of conservatism across species in the majority of sites, because these have a higher chance of each site being aligned to its homolog in other species. If the alignment for a set of sequences or parts thereof is difficult with much ambiguity, e.g., evidenced by particularly “gappy” alignments (as with Alignment 2 above), then such data may be dropped from the analysis. There are several software tools to automatically drop such sites from analysis, e.g., GBlocks (Castresana, 2000).

Multiple sequence alignment (MSA), for more than two sequences, is known to be computationally intractable: To guarantee an optimal scoring alignment even under the relatively simple affine scoring method above, requires an amount of space and time that grows exponentially with the number of sequences. Therefore for MSA the typical approach is to use one or more of a suite of well-established heuristic sequence alignment methods, such as MAFFT (Katoh *et al.*, 2002), muscle (Edgar, 2004), k-align (Lassmann and Sonnhammer, 2005), and T-Coffee (Notredame *et al.*, 2000) and often to then adjust their outputs “by eye”. Heuristic methods do not guarantee optimality (unlike for pair-wise alignment), and may not always yield the same output. For example two separate runs of any of these programs may in principle yield two different alignments, particularly if there are any equally high-scoring options, as ties have to be resolved either arbitrarily (giving rise to unbiased but inconsistent behaviour) or deterministically (giving rise to consistent, but biased behaviour).

MSA, or often “sequence alignment” or even simply “alignment” – context notwithstanding – just like pairwise alignment, has the aim of associating individual positions along every sequence with corresponding positions in the other sequences, such that each position corresponds to the same evolutionary history.

It is in principle possible to combine MSA with tree estimation, but these methods have yet to become standard in the phylogenetics community.

While the multiple alignment problem is computationally too demanding to solve perfectly, current heuristic methods can be very fast and reliable: Using default parameters that are moderately well tuned, it is entirely possible to perform this part of the phylogenetic inference workflow quite quickly, and without inspecting the data at all. *Caveat emptor*.

For protein coding genes, more complex alignment methods exist that take into account the three-dimensional structure of the proteins.

The oldest, but largely superseded, automatic alignment program is Clustal (Higgins *et al.*, 1992). It has default values of a gap opening cost of 10.0 and a gap extension cost of 0.1, so a gap of length 3 nucleotides has a cost of 10.3 by default.

In general the gap opening and extension costs can have different best values for different data sets (see Fig. 3).

Common Assumptions in Molecular Phylogenetics

In any inference process we must make assumptions. In phylogenetics these assumptions are mostly incorrect, but it turns out we can get away with making them in many situations. Some of the major ones are listed below:

The Sequences are Homologous

For many organisms, there is only one copy of any given gene, or of some other phylogenetic useful marker. However in eukaryotes (classically, haemoglobins in primates), it is not a safe assumption that genes that encode corresponding proteins across multiple organisms are necessarily homologous: They could be paralogous, that is, their most recent common ancestor might be before the most recent common ancestor of the organisms themselves (see Fig. 4).

The Alignment is Correct

Partly as a result of the computational complexity of inferring a tree from an alignment, it is rarely possible to move forward with phylogenetic inference without assuming that the alignment is good enough and moving on. Therefore the usual practise is to treat the alignment as fixed, and then undertake the even harder task of inferring the phylogeny based on it.

There are some methods available that attempt to perform MSA and tree estimation concurrently – but these are very lengthy approaches, and it is not yet clear that they are an ideal solution, particularly for large data sets.

Fig. 4 The species tree here (thick pipes) has a gene tree within it that is not congruent: The two left-most genes, for *a* and *b*, are paralogous: Their last divergence is before the divergence of their host species.

Sequence Evolution is Independent and Identically Distributed

This is the most ubiquitous of assumptions made in molecular phylogenetics and is the most often realised as patently false. It states that each site in a sequence evolves in the same way, and independently of, its neighbor. A moment's thought reveals that this cannot be true: In codons first, second and third positions have different selective constraints on them. Loci that code for microRNAs (miRNAs) will have sites within them that, if they change, must change in concert else they will destroy the ability of the miRNA to fold correctly. In protein-coding genes the bulk of evolving sites correspond to amino acids that interact with others. There are many cases where concomitantly varying sequences must be a better reflection of reality than the i.i.d. assumption (Lockhart *et al.*, 1998; Wang *et al.*, 2006) but yet for practical purposes it is often still useful to make this simplification: To a great extent the huge success of molecular phylogenetics is down to the flood of phylogenetically informative data that permit the robust estimation of phylogenetic history despite this incorrect assumption.

Time is Continuous

Biologically speaking, it does not make sense that time be treated as a continuous quantity: mutations occur at discrete time points such as cell division after all. But it is an assumption that we can get away with (as we do with the i.i.d. assumption), because in most cases the evolutionary changes occur at such a gradual pace in comparison with the time periods over which we measure them, that it may as well be modelled as a stochastic process in continuous time.

The mathematical benefits are significant for moving to continuous time, as we can employ tools from stochastic modelling such as the exponentiation of rate matrices to produce probabilities of change over arbitrary time periods. Without the assumption of continuous time, we really could not do phylogenetic estimation in any statistically justifiable way, but an assumption it is and for completeness, it is included here.

Time-Reversibility

Until recently almost all models of molecular evolution have worked under the assumption that evolution does not care about the direction of time: The probability of changing from one nucleotide to another in a given time interval is always exactly the same as that probability in the reverse direction.

Clearly this is not biologically correct! As soon as one understands that there can be selection toward a particular sequence then reversibility is broken. However, this is a crucial simplification that enables the likelihood of a set of aligned sequences under a model to be calculated regardless of where the root of the tree might be: Without the assumption, we must in principle calculate the likelihood from every possible location of the root, a considerable computational burden.

Tree-Like Evolution

Possibly the most famous phylogenetic tree is that which was sketched by Charles Darwin in his book "On the origin of species" (Darwin, 1859), with the telling note, "I think." Darwin was clearly imagining the formation of new species by a process of branching, with the possibility of lineages (species) going extinct, but not in terms of them converging again.

This is an important point because, if it is true (and it mostly is), it means that *trees* are the objects that we must use to represent species' origins. If we do not adopt this idea wholly, then we must permit more complex structures, in which there could be multiple paths from a common ancestor to some descendant. In a tree, all paths are unique – this can fact be part of the definition of what a mathematical tree is: A network connecting a collection of objects, such that there is always *exactly* one path between every two such

objects (see later; other places in the book). For the most part, phylogenetic inference (whether using molecular data or anything else) makes this assumption, but there is (often heated) discussion in the scientific literature as to the extent of non-tree-like evolution, caused by such mechanisms as lateral/horizontal gene transfer (LGT, HGT respectively) and hybridization.

Therefore if we think trees describe evolutionary relationships, we need to use the tools of branching processes in order to describe them. All this discussion so far is regarding a process that is moving forward with time, but there are also a wealth of tools to be employed if we look backwards. These latter tools use the concept of lineages *coalescing* as we move into the past, and they continue to yield powerful results that enable researchers to understand better the way species, and particularly lineages within species, emerge.

Another generalisation that we must consider is non-treelike evolution, corresponding to lineages converging, e.g., by hybridization or horizontal gene transfer. In phylogenetics these representations are usually referred to as *networks* (though to a mathematician, all trees are also networks).

For the moment we restrict ourselves to phylogenies as trees (but see later).

Further, we constrain our thinking to trees in which speciation events always give rise to exactly two “new” lineages – such trees are called *binary*, and differentiate between those with a chosen root and those without one (see Time and Reversibility).

Non-Tree-Like Evolution

A given site is assumed to evolve according to a tree-like pattern, only branching as they move forwards in time, but there are other units of evolution that can converge instead. For example, genes may be horizontally (or “laterally”) transferred from one species to another (Berghorsson *et al.*, 2003), and species can hybridize (Harrison and Larson, 2014). In those cases the genes may not share the same evolutionary histories, and the species phylogeny is better represented as a hybridization network.

An alternative is that due to uncertainty in the phylogenetic signal, even though the tree history may be tree-like (branching), it is desired to show a range of alternative hypotheses in the same figure. These phylogenetic networks can illustrate support for branching patterns and splits of the taxa of interest that are conflicting: They cannot both be part of a tree, but they can be shown as, for example, a “NeighborNet” (Bryant and Moulton, 2003). NeighborNets have become a standard tool in molecular phylogenetics. Their construction is based on estimates of pair-wise distances between taxa, rather than on a scoring method for a tree.

What Makes a Tree a Good Tree

Because of the vast number of possible trees, growing super-exponentially in the number of taxa involved, it is a virtual certainty that the estimated phylogeny for very large sets of taxa will be incorrect – somewhere. However, that is not to say that everything in the tree is wrong. It is helpful to think of a phylogeny as a set of non-independent hypotheses of relatedness, many of which may be correct!

For example in Fig. 4 there are several hypotheses displayed:

1. A and B are each others’ closest relatives and form a monophyletic group (a.k.a. clade);
2. A, B and C are monophyletic/form a clade;
3. B and C are paraphyletic in this tree.

A very standard method of measuring robustness of a phylogeny is via *bootstrapping*, which is a method by which sites in an alignment are sampled at uniform random and with replacement, in order to create “pseudo-replicates” of the original data set (Efron *et al.*, 1996). Each pseudo-replicate is then subjected to the same inference methods as for the original data set, and for each tree inferred on the pseudo-replicates, a note is made of which branches are in that tree. The proportion (or percentage) of times in which each branch is recovered is a measure of the phylogenetic consistency of the data.

The philosophy behind such resampling – leading to the idea of “pulling oneself up by one’s bootstraps” is that, if the observed (assumed to be homologous, and independently evolving) sites were representative of a larger population of such sites, then resampling from them would be equivalent to resampling from that larger population. This is a strong assumption, so interpretation of the resulting bootstrap values must be done with care. It is technically not a measure of confidence, as such, as it is possible to gain arbitrarily large bootstrap values simply by having large data sets (Jermini *et al.*, 2005), but in general high values (e.g., 80% or more) are taken to be indications that the data are providing strong signal in favour of a particular branch.

Choosing the Best Tree

In order to select the tree that is the best possible explanation of the evolutionary relationships among a set of species, we must be able either to construct the tree according to some algorithm, such as Neighbor-Joining (Saitou and Nei, 1987; Studier and Keppler, 1988; Gascuel and Steel, 2006), or to evaluate each tree with some kind of score function and search through the space of all possible trees for the one(s) that maximise(s) the score. Next we discuss the two main score functions for trees, and then discuss tree searching.

In order to recover a tree from molecular sequence data we must have in mind some model that effectively describes what we know about sequence evolution. Models arise from different philosophies, and in molecular phylogenetics, the two main ones are that of maximum parsimony, and of (probabilistic) likelihood. Both of these ideas require a search through tree space: the set of

all possible trees that relate the set of taxa of interest, with trees being considered as adjacent with respect to some perturbation if one can be modified to match the other.

Maximum Parsimony

According to *maximum parsimony*, also referred to as Occam's Razor, it is the simplest explanation that is the best explanation of what happened. The origin of this idea is ancient, but it still has some value in modern science, provided one recognises its limitations.

Fitch (Fitch, 1971) devised an ingenious algorithm that counts the minimum number of changes of state that are required on a given tree in order to explain the sequences observed at its tips. The total Parsimony score – Also called the Parsimony *length*, is the sum of the minimum number of changes that must occur on the tree to account for the characters at the leaves of the tree, and it is this score that is to be minimised over all possible trees.

The algorithm is performed on each site in turn and the score (length) for site is accumulated into the total. (Obviously, one can speed things up by calculating it only on unique site patterns and then multiplying by the number of times it occurs, and there are other optimisations possible, but they are not illuminating here; the interested reader is directed to).

Fitch's algorithm was later shown to be a special case of a more general algorithm of Sankoff (Sankoff, 1975), which can also take into account weights for different substitutions. Sankoff's algorithm requires slightly more bookkeeping, in that one must calculate and retain the minimal total cost for every possible character state at each node, but it is beyond the scope of this brief article to go into that detail; the interested reader is directed to Sankoff (1975).

The Fitch algorithm is outlined in **Box 2** for rooted binary trees on nucleotide data.

Box 2: Algorithm for calculating the Parsimony length of a tree

Algorithm 1: ParsimonyLength(T, A)

```

given  $T$ , a rooted tree with tips labelled  $1, \dots, n$ 
given  $A$ , an aligned set of  $n$  observed sequences of length  $\ell$ 
let  $r$  be the root node of  $T$ 
let  $p$  be the parsimony length of  $T$ 
let  $V$  be the set  $V = \{v_1, \dots, v_{n-1}\}$  of non-leaf nodes of  $T$ 
 $p \leftarrow 0$ 
for each ( $i = 1, \dots, \ell$ ) do {
  ·  $p \leftarrow p + \text{Fitch}(r, A, i)$ 
}
return( $p$ )

```

Algorithm 2: Fitch(v, A, i)

```

given  $v$ , a node in a rooted binary tree
given  $A$ , an aligned set of  $n$  observed sequences of length  $\ell$ 
given  $i$ , the position of a site of interest in  $A$ 
let  $F(v)$  be the character state(s) assigned to  $v$ 
let  $q$  be the Parsimony score of this site
 $q \leftarrow 0$ 
if ( $v$  is a leaf) then {
  /*  $F(v)$  is our observed data */
  ·  $F(v) \leftarrow A_{i,v}$ 
  · return(0)
} else {
  · let  $S$  be a set of states allowed (e.g., A, C, G, T)
  ·  $S \leftarrow F(v.\text{leftchild}) \cap F(v.\text{rightchild})$ 
  · if ( $S = \emptyset$ ) then {
    ·  $q \leftarrow q + 1$ 
    ·  $S \leftarrow F(v.\text{leftchild}) \cup F(v.\text{rightchild})$ 
  }
  ·  $F(v) \leftarrow S$ 
}
return( $p$ )

```

For example, consider again the alignment that corresponds to the tree in [Fig. 1](#):

taxon	sequence
d	TCGC
e	TTGT
f	ACGT
g	AG-A
h	GC-C

There are five possible states: A, C, G, T, and the “gap” state -. Consider the first site pattern, TTAAG for the five taxa d, e, f, g, h in order. For this part we use the notation $(a)=X$ to mean node (a) has character state X. Proceeding from the leaves of the tree to the root, we first consider node (c), which has the two child nodes and character states (d) T and (e) T. $\{T\} \cap \{T\} = \{T\}$, so we assign T to node (c). Moving up to node (a) which now has children (c)=T and (f)=A. $\{T\} \cap \{A\}$ is empty so we set $(a) = \{A, T\}$ and add 1 to the Parsimony length of this tree. Next is node (b), which has as its child nodes (and character states) (g)=A and (h)=G. Again we find the intersection of these two sets of character states is empty so we increment the Parsimony length and assign $(b) = \{A, G\}$. The last node is the root, which now has children $(a) = \{A, T\}$ and $(b) = \{A, G\}$. Since $\{A, T\} \cap \{A, G\} = \{A\}$ is non-empty, we assign A to the root node. The Parsimony score for this site is 2.

To calculate the Parsimony score for the complete alignment we repeat the process over the other three site patterns; and if we wish to account for different costs of different substitutions, we can keep track of all possible character states at all the nodes, and retain their minimal scores as we move “up” the tree to the root.

Maximum Likelihood

By far the most common tool used currently to infer molecular phylogenies is maximum likelihood (ML). This is a simple concept but one which has grown to comprise a very rich suite of models and methods. We begin with a toy example to illustrate the key concepts and then mention some (but not all) ways in which it is generalised.

The essential idea of maximum likelihood (ML) is that under a probabilistic model, we may calculate the probability of observing a given outcome. The given outcome we choose is our set of observed data: That is, a set of aligned sequences. The simplest possible model for illustration purposes is a two-state one, in which we have sequences of 0s and 1s, evolving according to a symmetric rate matrix

$$Q_{CF} = \begin{bmatrix} -\alpha & \alpha \\ \alpha & -\alpha \end{bmatrix}$$

This matrix is labelled “CF” as it corresponds to the Cavender-Farris model ([Cavender, 1978](#)) Rate matrices correspond to limits of instantaneous probabilities of change from one state to another; but to calculate an actual probability for a given time period, we must convert from rate matrices to probabilities.

Assuming a Poisson process for mutation events we can determine that for a rate matrix Q operating over a time period t , the probability matrix that corresponds to changes of state over that time period is given by $P = \exp(Qt)$. In the case that Q is conveniently exponentiated this leads to closed forms that can be used to calculate the probability of a given (e.g., nucleotide) state into another, conditioned on that rate matrix being correct.

The above instantaneous rate matrix Q is called doubly stochastic: Both its rows and its columns individually sum to zero. Doubly stochastic models have the property that the steady state distribution of character states is uniform: In this case, our two character states will settle over a long enough period to occur in equal proportions. In the case of DNA models that are doubly stochastic, we expect their nucleotide base frequencies to tend to $(\frac{1}{4}, \frac{1}{4}, \frac{1}{4}, \frac{1}{4})$.

The probability matrix that corresponds to this rate matrix is given by

$$\text{Exp}(Q_{CF}t) = \frac{1}{2} \begin{bmatrix} 1 + e^{-2\alpha t} & 1 - e^{-2\alpha t} \\ 1 - e^{-2\alpha t} & 1 + e^{-2\alpha t} \end{bmatrix}$$

For the next simplest model, still doubly stochastic but with four states, we have

$$Q_{JC} = \begin{bmatrix} -3\alpha & \alpha & \alpha & \alpha \\ \alpha & -3\alpha & \alpha & \alpha \\ \alpha & \alpha & -3\alpha & \alpha \\ \alpha & \alpha & \alpha & -3\alpha \end{bmatrix}$$

yielding

$$\text{Exp}(Q_{JC}t) = \begin{bmatrix} 1 + 3e^{-4\alpha t} & 1 - e^{-4\alpha t} & 1 - e^{-4\alpha t} & 1 - e^{-4\alpha t} \\ 1 - e^{-4\alpha t} & 1 + 3e^{-4\alpha t} & 1 - e^{-4\alpha t} & 1 - e^{-4\alpha t} \\ 1 - e^{-4\alpha t} & 1 - e^{-4\alpha t} & 1 + 3e^{-4\alpha t} & 1 - e^{-4\alpha t} \\ 1 - e^{-4\alpha t} & 1 - e^{-4\alpha t} & 1 - e^{-4\alpha t} & 1 + 3e^{-4\alpha t} \end{bmatrix} = \frac{1}{4} \begin{bmatrix} 1 + 3\beta & 1 - \beta & 1 - \beta & 1 - \beta \\ 1 - \beta & 1 + 3\beta & 1 - \beta & 1 - \beta \\ 1 - \beta & 1 - \beta & 1 + 3\beta & 1 - \beta \\ 1 - \beta & 1 - \beta & 1 - \beta & 1 + 3\beta \end{bmatrix}$$

where $\beta = e^{-4\alpha t}$.

The most general time-reversible model is known as GTR, the General Time-Reversible model (Tavaré, 1986). GTR parameters can be expressed simply as the equilibrium base frequencies a four-dimensional vector $\pi = (\pi_A, \pi_C, \pi_G, \pi_T)$ whose non-negative entries sum to 1, and a rate matrix

$$Q_{GTR} = \begin{bmatrix} -(\alpha\pi_C + \beta\pi_C + \gamma\pi_T) & \alpha\pi_C & \beta\pi_C & \gamma\pi_T \\ \alpha\pi_A & -(\alpha\pi_A + \delta\pi_C + \varepsilon\pi_T) & \delta\pi_C & \varepsilon\pi_T \\ \beta\pi_A & \delta\pi_G & -(\beta\pi_A + \delta\pi_G + \eta\pi_T) & \eta\pi_T \\ \gamma\pi_A & \varepsilon\pi_G & \eta\pi_C & -(\gamma\pi_A + \varepsilon\pi_G + \eta\pi_C) \end{bmatrix}$$

where a moment's inspection reveals that if $\pi_A = \pi_C = \pi_G = \pi_T = 0.25$ and $\alpha = \beta = \dots = \eta$, we recover the Jukes-Cantor model as a special case.

The most general model possible for DNA is the General Markov Model, which is exactly as it sounds: Simply a general Markov model on four states.

Matrices like those above can yield well defined probabilities of change from one state (nucleotide) to another given a certain amount of time. This is the basis of constructing the likelihood on a complete tree, as follows: Consider a branch in a tree, with some length ℓ . We may sum over all the possible character states at the ends of this branch and, for each possible combination, calculate the probability of change from the state at one end to the state at the other. Felsenstein created an efficient "pruning algorithm" to do this calculation for a complete tree, over all possible internal character states (in the case of DNA, nucleotides) in the tree, by only keeping track of four possible states at each node, representing the maximum possible likelihood of character state assignments in its descendants (Felsenstein, 1973). The branch lengths and the model parameters (α , β etc. above) directly affect the likelihood. Thus an ML search for the best tree is a process that should in principle search over all possible sets of branch lengths, and all possible sets of parameter values: The computational task is immense.

There are hundreds of possible matrices for DNA, and more of course for amino acids or codons. The decision on which model to choose is often a difficult one, and various approaches have been devised to help. Early in the relatively short history of maximum likelihood applied to phylogenetic inference, likelihood ratio tests were used to compare nested models. The JC model above is a special case of the GTR, but they differ in the number of free parameters (JC can be considered as having just 1 parameter, and GTR 9: They differ by 8 free parameters). Twice the difference in log-likelihoods is known to be χ^2 -distributed, with degrees of freedom equal to the difference in the number of their free parameters, so this method has been used successfully to guide the researcher through a decision tree in the well-cited program, ModelTest (Posada, 2008). This approach has its limitations though, and a standard scheme is now to determine for a given tree the Akaike Information Criterion (AIC) score or one of its derivations (AICc, BIC) to give for each model a simple score, and the researcher may then choose that which has the best score. This avoids the computational complexity of comparing every possible pair of nested models, and enables comparison of models that are not nested.

In general constructing a tree from an algorithm is considerably faster than searching through tree space, taking in the order of $O(n^3)$ operations over all, with n taxa. To search the entirety of tree space is prohibitive: The number of trees increases with n , the number of taxa, at a rate approaching n^n (exact numbers below); hence for all but the most moderately sized examples, we must use heuristics.

Searching Tree Space

The Fitch and Sankoff algorithms solve the "Small Parsimony Problem" – Finding the minimum number of changes that are required to explain an alignment on a tree. The related "Large Parsimony Problem" is that of finding that tree that has the best score, out of all $(2n - 3)!!$ possible rooted binary trees on n taxa (though in fact, as we are regarding the substitutions as equally costly in either direction, we can treat the tree as unrooted, and there are "only" $(2n - 5)!!$ of those). Similarly if the score function is likelihood we are faced with the corresponding problem: find the tree (with branch lengths and other model parameters) that has the highest likelihood of generating the data we observed.

The Large Parsimony Problem, and the tree search problem in general, is solved using local search, typically hill-climbing or simulated annealing. The starting tree is usually constructed quickly using Neighbor-Joining (NJ) or similar. The hill-climbing search operates by perturbing the current tree in some well-defined way and calculating score of the perturbed tree. Hill-climbing is relatively fast among local searches, but it has the obvious problem that if the landscape of the search space has multiple peaks (optima) then it can become stuck in one of them that is not globally optimal. There are several ways that have been developed to get around this issue, including performing multiple hill-climbing searches from different starting points, and using more sophisticated methods such as Simulated Annealing (Van Laarhoven and Aarts, 1987) and Tabu Search (Glover, 1989). Even with these more sophisticated methods it is not possible to guarantee that the best tree has been found.

Note also that our choice of score function, whether it be Maximum Parsimony or Maximum Likelihood, has to be viewed as an approximation to “best” – the assumption is that the tree that optimises the score we choose is the correct one. Many studies find that the most parsimonious tree (that with the lowest Parsimony length) is not the same as the most likely tree (that with the highest conditional probability of having generated the observed sequences). Therefore a common practise is to perform multiple tree searches with different objective functions and hope for consensus.

Time and Reversibility

The presence of a root induces a sense of direction – away from the root and toward the tips, corresponding to increasing time. Rooted trees must be a better representation of evolutionary dynamics, because time does indeed move forward.

However, most – if not all practised – methods that are used in phylogenetic inference assume that there is no inherent direction implied by any of our molecular data: For example there is no sense in which it is quicker or easier to go from A to B than it is from B to A. These models are referred to as time-reversible: The measure of evolutionary work that must be done, or the probability of a given train of sequence evolution, is independent of whether we are moving in the positive or negative time direction.

Thus, the inferred phylogeny we initially create using methods such as maximum likelihood or maximum parsimony (see later), are perforce unrooted. Since rooted phylogenies are so desirable, we must therefore also have methods to determine where the root is.

Rooting trees can be achieved in several ways, in general based on the idea that sequences have diverged from some kind of mean, and/or, at an approximately constant rate (see later). If all the sequences have evolved at approximately the same rate as each other, then we can expect them to be approximately the same distance from their common ancestor, which would, if the branches of the tree accurately reflect evolutionary time, be in the middle of the tree in a well defined way. A simple approach to rooting the tree then is to find the point on the tree that corresponds to the average of the half-way points between every pair of leaves.

Bayesian Methods and Markov Chain Monte Carlo

Thomas Bayes’ Theory has become a central tool in molecular phylogenetics as it enables the use of prior information to be correctly incorporated into a likelihood estimation. In phylogenetics, Bayes’ Theorem takes the form of priors on model components such as the set of possible phylogenetic trees, prior probabilities of particular sequence evolution models or their parameters, or on certain dates of divergence.

For example we might have some estimate on the probability distribution of phylogenetic trees on a taxon set: It could be that “all trees are equally likely” prior to our analysis (a model that has no biological realism it must be said), or that trees arise under a standard birth/death process; the Yule model (Yule, 1924). These priors modify the posterior probability that the data arose from particular models, and enable researchers to make much more powerful conclusions about the phylogenetic relationships under study, including estimates of population size, divergence times based on fossil calibrations, and selection.

Bayesian inference has come to the forefront of phylogenetic inference through such programs as MrBayes (Huelsenbeck and Ronquist, 2001) and BEAST (Drummond *et al.*, 2012). These programs perform Markov chain Monte Carlo analyses and enable researchers to sample from the posterior distribution of trees estimated, and inferences made based on the relative likelihoods of these trees. For example given a posterior distribution of trees, each with their posterior probability, a weighted average can be formed of the overall age of the tree.

What can go Wrong

Given that there are so many components to inferring phylogenies – and the difficulty in verifying that a given phylogenetic inference is even correct – it’s no surprise that there is a veritable cornucopia of things that can go wrong. Here is a non-exhaustive list, in no particular order:

1. *Alignment error*: It is entirely possible that the alignment is wrong. Many authors attempt to avoid this possibility by removing areas of the alignment that are in particular doubt (highly “gappy” loci for example) or, less commonly, by performing analyses with different plausible alignments.
2. *Bad calibration (mutation rates)*: Good fossil records can afford useful prior probability distributions on divergence dates, but it is known that the choice of prior can have a significant effect on the accuracy of divergence time estimations in phylogenetics. Suggested ways around this problem include testing over a range of priors, more stringent screening of calibration points, and sub-sampling from the fossil calibration points to gauge sensitivity of the phylogenetic estimation.
3. *Covariation model*: Our most basic assumption is that sites evolve independently on a sequence, and we can in general get away with this. However there are cases where this assumption is violated and it has an effect on our tree estimation.
4. *Heuristics have no guarantees*: It is worth remembering that heuristic methods have no guarantee of producing an optimal solution. It’s also known that there can be many cases where even our most favoured phylogenetic scoring systems (parsimony, Likelihood) may well have multiple optima for the same data set: there can easily be cases where more than one tree has an optimal likelihood or parsimony length. This not only means that heuristic search methods can become accidentally stuck in

- the wrong places (globally optimal or not), but also that even if all the globally optimal solutions could be located, we would still have the troublesome task of choosing the best among equals.
5. *Incomplete burn-in for MCMC*: Markov chain Monte Carlo requires a burn-in to escape poor areas of the likelihood landscape and navigate to those areas that contribute significantly to the likelihood mass of phylogenies that could have given rise to our observed data. It is entirely possible – in fact it may be common – that burn-in proceeds in jumps, with long periods of proposed moves during which there is no major change in parameter values, followed later by location of new plateaus in “better” regions of tree space (Nylander *et al.*, 2007).
 6. *It's not a tree after all*: As mentioned above, it's possible that by combining phylogenetically informative sequences from different loci, such as genes, we are combining incongruent trees: In such cases the conflicting trees should be reconciled with a single species tree; often through consensus methods.
 7. *Long branch attraction*: Long branches give sequences a chance to converge towards each other simply by chance. Consider a tree in which all but two branches are short, yet the two long ones are not each other's closest relatives. Under such circumstances the two sequences at their leaves may look more like each other simply by dint of the other sequences being less diverged. This phenomenon is known as long branch attraction.
 8. *Model mis-specification*: Getting the underlying model “wrong” runs the considerable risk that the tree is also incorrect (Jermini *et al.*, 2006).
 9. *Rates across sites*: individual sites may evolve under different conditions and so modelling them as though they all evolve at the same rate is an error.
 10. *Saturation of sites*: The alphabet of available character states is very restricted: In DNA and RNA it is only 4 states, so accumulating many changes among those states renders sequences effectively random with respect to each other. If the steady state distribution of nucleotide frequencies is uniform (e.g., if the molecular evolution model is doubly stochastic) then the expected distance between sequences will tend to 0.75 as time increases.
 11. *Software error*: Testing bioinformatics software is often complex and difficult, because testing is ideally done using an “oracle” – A ground truth against which we can test, and there are few such oracles in bioinformatics. While the software currently forming the standard set of tools for phylogenetic inference is in general quite well established and tested by its large user base, it is wise to exert caution when using new software, which may not have had such rigorous testing.

Further Reading

The interested reader is directed to some excellent texts and a wealth of publications in the scientific literature. Joe Felsenstein's “Inferring phylogenies” (Felsenstein, 2004) remains a classic work that is highly readable and yet comprehensive. Nei and Kumar's “Molecular Evolution and Phylogenetics” (Nei and Kumar, 2000) is another detailed work that goes into detail of molecular evolution in amino acids and in nucleotides, discusses phylogenetic inference in far more detail than can be achieved in this short article, and includes material on population genetics. Page and Holmes' “Molecular Evolution: A Phylogenetic Approach” (Page and Holmes, 1998) is a slightly earlier work that remains informative, beginning with a focus on genome evolution as a whole, and the how function relates to evolution. Wen-Hsiung Li's simply titled “Molecular Evolution” (Li, 1997) is from around the same time, and while it also discusses molecular phylogenetics spends a great deal more time on different mechanisms of molecular evolution. Moving into the more mathematical side, Olivier Gascuel's edited book “Mathematics of Evolution and Phylogeny” (Gascuel, 2005) touches on a variety of topics that were not covered here (as well as most that were), including the elegant Hadamard Conjugation method of phylogenetic analysis, mixture models, and even reconstruction of phylogenies from distances estimated by genome rearrangements. Mike Steel and Charles Semple have produced “Phylogenetics” (Semple and Steel, 2003) – Which is largely mathematical work suitable for the mathematician, and “Phylogeny: Discrete and Random Processes in Evolution” (Steel, 2016) is a further example of enjoyable, yet dense, mathematical writing. Yang's “Molecular Evolution: A Statistical Approach” (Yang, 2014) is a more modern piece that is rigorous and accessible. Finally, Drummond and Bouckaert's “Bayesian Evolutionary Analysis with BEAST” (Drummond and Bouckaert, 2015) is an excellent handbook for this sophisticated program, which is one of the standard tools of phylogenetic inference.

Software

Molecular phylogenetics is impossible without good software. Among the standard tools are, in no particular order, BEAST and MrBayes (Bayesian analysis), PhyML and IQTree (Maximum likelihood methods), PHYLIP, PAUP and MEGA (complete suites of methods).

Introduction

In evolutionary biology, differences are observed between closely related species, both in their genotype and aspects of their phenotype. Alignments of homologous characters (those descended from a common ancestor), and corresponding phylogenetic trees that show the ancestral relationships between entries in the alignment, are commonly used to characterize the evolutionary process. In moving from sets of homologous characters to characterizations of evolution, explicit models of the evolutionary process are commonly used. These models describe the probabilities of different types of evolutionary changes allowing the most likely trajectory to be identified. The models are frequently structured as Markov processes. Evolutionary models can be applied to data at multiple levels of biological organization, from morphological change, to gene content in genomes, to gene duplication, to genetic sequence data. This article will focus on models for biological sequence evolution.

Multiple sequence alignment is one problem where evolutionary models are particularly useful. Probabilities of different types of sequence change are compared with the probabilities of an insertion or deletion having been introduced (commonly using affine gap penalties) to generate an alignment of sequence characters (DNA or protein) that derived from a common ancestor (Anisimova *et al.*, 2010). There are many methods to infer phylogenetic trees based on multiple sequence alignments, many of these methods are based on explicit models of sequence change. The phylogenetic tree shows the branching pattern of descendent sequences (from species or gene copies within a genome), with internal nodes reflecting ancestral character states. Branch lengths are estimated as well, with units of expected changes per site under the model as the most common units. Inference of sequences at internal nodes is a sub-field of its own, known as ancestral sequence (state) reconstruction. Lastly, models are also used in the search for lineage-specific positive selection, in characterizing the patterns of sequence change on particular branches of a phylogenetic tree (Benner *et al.*, 2007).

Because alignment and phylogenetic analysis both rely on models of the same evolutionary process, one strategy that has been developed, but is not currently widely used, is to simultaneously estimate both. Not only does this enable the consistency of using the same model for the evolutionary process in both steps, but it also enables accounting for alignment uncertainty in tree estimation. *Baliphy* is an example of an approach implemented in a Bayesian statistical framework that uses models to simultaneously estimate alignments and trees (Redelings and Suchard, 2005).

Markov Models

Models of sequence evolution range from phenomenological models that are designed to fit data as well as possible with as few parameters as possible, to mechanistic or generative models that are designed to model the process generating the data. The mechanistic models may not describe data as well as the phenomenological models on interpolated data, but may enable extrapolation to longer evolutionary distances in cases that might be prohibitive for phenomenological models (Liberles *et al.*, 2013). Because mechanistic models are meant to describe the process, there is the expectation that they will have predictive value on data that they were not fit to.

In order to model the evolution of molecular sequences, some key simplifying assumptions are made in almost all cases. A strong assumption that provides great benefits in terms of the tractability of models is that the evolution of different sites in an alignment is independent and happens according to a common process – this is known as the i.i.d. assumption (independent and identically distributed). The second assumption is that sequences evolve according to a Markov process. This means that the evolution of a particular character depends only on its current state rather than on any additional information about the past states.

With these assumptions in place, sequence evolution can be modeled with a continuous time Markov chain (CTMC). In the case of modeling sequence evolution for DNA, amino acids, or codons, the state space is discrete, e.g., for DNA the state space is {A, C, G, T}. The instantaneous rates at which any particular character state substitutes into any other state can be gathered into a rate matrix, Q , sometimes known as the generator matrix. If these rates are in effect for time t then the probability of a transition from state i to state j is given by the ij th entry of the matrix P , where $P = \exp(Qt)$.

Given an edge-weighted phylogenetic tree and a continuous time model given by Q it is possible to calculate the probability of observing any particular site pattern at the tips of the phylogenetic tree in extant sequences (Felsenstein, 2004). This means such models can be used as a basis for likelihood or Bayesian style statistical approaches to determine which choice of tree and edge weights give the highest probability of producing a particular sequence alignment.

A sequence alignment reflects the collection of substitutions that result from mutations. It should be noted that the term *mutation* formally refers to a mutation introduced to a population at frequency $1/N$ in a haploid population. When this mutation fixes (goes to frequency 1), this is referred to as a *substitution*. Inter-specific evolutionary models are designed to model substitution rates and processes. If sequences are evolving neutrally then the rate of mutation and substitution are the same (Kimura, 1983),

but if sequences are under selection then the distinction between mutation and substitution is an important modeling consideration.

Parameterized DNA Models

Standard DNA models (see [Felsenstein \(2004\)](#) for a further discussion of standard models and their original references) started with the Jukes-Cantor model ([Jukes and Cantor, 1969](#)), which has a single rate parameter that describes the equal probability of exchange between all bases. From a statistical perspective, this is a natural model that characterizes the rate of change without any biological assumptions. However, from a biological perspective, this model tends to explain sequence substitution patterns poorly. The Kimura 2-parameter model ([Kimura, 1980](#)) is a standard model in the hierarchy of models that differentiates between transitions (substitutions between purines or between pyrimidines) and transversions (substitutions that convert between purines and pyrimidines). The reason this is natural is that transitions are more likely due to oxidative deamination (at least for C to U changes) and due to polymerase error, and also because of the genetic code, where 2-fold degenerate codons preserve the encoded amino acid with a transition but not a transversion.

Another introduction of model complexity that is similarly nested over the Jukes-Cantor model involved the introduction of unequal base equilibrium frequencies with a single rate parameter to produce the ([Felsenstein, 1981](#)) model. One example of the importance of unequal equilibrium frequencies is the hypothesis of temperature dependence to GC usage because of its effect on DNA melting temperatures ([Groussin and Gouy, 2011](#)). The parameters of K2P and F81 were combined in the HKY model ([Hasegawa et al., 1985](#)). A further relaxation of this involves the GTR model ([Lanave et al., 1984](#); [Tavaré, 1986](#)), where each of the six inter-conversions has an independent rate parameter.

GTR is the most complex model that is time-reversible such that, given the equilibrium base-frequency distribution $\pi = (\pi_A, \pi_C, \pi_G, \pi_T)$, $\pi_i Q_{ij} = \pi_j Q_{ji}$. A further relaxation from six to twelve rate parameters gives the General Markov Model (GMM) ([Barry and Hartigan, 1987](#)), which is not time reversible. This set of standard models is summarized in [Fig. 1](#). Between Jukes-Cantor and GTR for symmetrical matrices and GMM to include non-symmetrical matrices, is a hierarchy of conceivable models ([Huelsenbeck et al., 2004](#)). The property of being time reversible makes models much more efficient to compute with ([Felsenstein, 2004](#)). To use non-time-reversible models, a rooted tree must be used and likelihoods calculated in a different manner ([Boussau and Gouy, 2006](#)). Despite this computational complexity, biologically one does not expect evolution to be time-reversible when the underlying processes are not in equilibrium and the changes are not neutral.

Commonly Used Additional Parameters

Additional parameters are commonly used together with phylogenetic Markov Models for DNA and for proteins. Parameters that change the equilibrium frequencies of the underlying model (particularly for empirical models described below) to fit those of the

Fig. 1 An overview of common DNA models is shown. Models with equal base-frequencies are shown with a blue background, models with free base-frequencies are shown with a green background. Models with the Lie-Markov property have a bold border. Models above the first dashed line allow a transition/transversion ratio. Models above the second dashed line allow 6 different substitution rates. Models below the third dashed line are time-reversible. Arrows directed from one model to another indicate that the model is a sub-model, i.e., that it is nested within the more complicated model.

dataset (+F) are commonly included as extra parameters. Additionally, some sites are of such (context-dependent) importance in a dataset that they show a substitution rate of zero over the period of evolution over which the data were generated. Modeling a fraction of invariant sites (+I) with substitution rate zero is another common parameter that is added to phylogenetic Markov Models.

More generally, different sites evolve at different rates, both due to variation in the mutation process and due to differential selection on different sites. There have been two main approaches to tackling this: mixture models and partitioned models. The most common application of mixture models is to use the gamma distribution (+G) to model rate heterogeneity across sites (Yang, 1994). A strength of this approach is that a single shape parameter can provide a continuum of models ranging from equal rates to very right-skewed rates. This is most commonly implemented using a discretization of the gamma distribution into four rate categories, although alternative mechanisms of using a gamma distribution are possible. No index parameters are included, i.e., sites are not allocated to particular rate classes, instead all four rate categories are used as a mixture process applied to all sites. Using a gamma distribution is somewhat arbitrary, a slightly more parameter-rich alternative is the free-rate model, which allows a mixture model over an arbitrary set of rates (Yang, 1995; Pagel and Meade, 2004; Mayrose *et al.*, 2005). The other strategy for dealing with heterogeneity is to use prior knowledge of the data, e.g., gene boundaries, positions within a protein structure, and/or codon position, to partition the sequence alignment and then fit different models to each part of the partition (Bull *et al.*, 1993).

Lie-Markov Models

Even with the extensions stated above, most phylogenetic applications of evolutionary models assume that a common process operates over all sites and in all parts of the evolutionary tree. This assumption does not appear to be biologically realistic. In particular, a prediction of such models is that base frequencies should be similar in all species under consideration, but this has been shown empirically not always to be the case (Jayaswal *et al.*, 2011). Codon models have also been used to show that evolution can be a heterogeneous process with evidence for selection acting in some branches but not others.

If one allows the possibility that the evolutionary process may be different in different edges of the phylogeny or differ along edges then this introduces an interesting consideration about how one might want the Markov models in use to behave. If one considers that evolution happens according to some rates Q_1 for some period of time t_1 followed by some rates Q_2 for time t_2 then one can work out the transition probabilities over time $t_1 + t_2$ to be $P = \exp(Q_2 t_2) * \exp(Q_1 t_1)$. A Markov model has the closure property if this matrix P can still be expressed as $P = \exp(Q t)$ for some Q chosen from our model. Many commonly used Markov models, including GTR and HKY, do not have this closure property. Recent work by Sumner *et al.* (2012) has developed a hierarchy of evolutionary models, known as Lie-Markov models, that are defined by having this closure property.

Model Selection

As discussed above, a common approach to add biological realism is to differentiate between types of nucleotide substitutions. For example, Huelsenbeck *et al.* (2004) consider all 203 possible partitions of relative rates for time-reversible models, reflecting all possible models of this class. Another approach is to consider that there are different classes of bases (e.g., AG and CT) and then use the resulting symmetries to find appropriate constraints on substitution rates (Fernández-Sánchez *et al.*, 2015).

Given the wealth of possibilities for parameterized models a problem that arises is how best to choose a model to fit a particular dataset. The best inference comes when a model is appropriately complex, with all of the necessary parameters, but without extra parameters that do not contribute to data fit and/or that can cause model mis-specification (Steel, 2005). An approach, initially proposed by Posada and Crandall (2001), was to perform likelihood ratio tests of nested models (see Fig. 1). More recently the field has moved to prefer information criterion biased approaches such as the Akaike Information Criterion (AIC) or Bayesian Information Criterion (BIC) (Posada and Buckley, 2004). The AIC score of a model depends on both the likelihood and on the number of free parameters in the model, $AIC = -2 \ln L + 2K$ where $\ln L$ is the log likelihood and K is the number of parameters. The BIC = $-2 \ln L + K \ln n$, where n is the sample size (e.g., the length of the alignment) this penalizes additional parameters more strongly than the AIC. For both AIC and BIC, models with smaller scores are preferred. A strong advantage of both the AIC and BIC is that they do not rely on models being nested. For partitioned models the number of possible models makes it prohibitive to check the AIC or BIC of all models and it is common to take a heuristic approach to finding models that fit well instead (Lanfear *et al.*, 2012).

Empirical Models

An alternative to using parameterized models to fit substitution data is to pre-calculate empirical substitution matrices from large datasets. This approach is commonly applied when working with amino acid as opposed to DNA data. One reason to do this is that while a maximal time-reversible DNA matrix can have up to 6 rate parameters, an equivalent matrix for proteins could have 190 rate parameters. Furthermore, some transitions between rare amino acids or those that are separated by two or three nucleotide changes in the genetic code occur too rarely to be able to estimate well from typical datasets.

The first instance of an empirical amino-acid model was produced by Dayhoff *et al.* (1978), they used closely related aligned proteins on a well-established phylogeny to estimate the rate at which particular amino acids substitute for other amino acids. Similar ideas were used by later authors although they tended to use much larger databases of curated alignments and to be more computationally intensive as they incorporated tree-estimation simultaneously with estimation of the empirical substitution parameters (e.g., JTT (Jones *et al.*, 1992), WAG (Whelan and Goldman, 2001), LG (Le and Gascuel, 2008), see also Zoller and Schneider (2013)). WAG included the innovation of maximum likelihood parameter estimation, while LG included the innovation of gamma distributed substitution rates.

A number of alternative matrices for either specific datasets, for specific attributes of protein structures, or statistically defined matrices have been created. A particular example of this is the set of empirical matrices for proteins that are partitioned by secondary structure and solvent accessibility (Koshi and Goldstein, 1995).

Codon Models

There is independent information that is encompassed in DNA models and in protein models and both sources of information can be harnessed when using codon models. Codon models can be built in three different broad types. The first type is to adopt a nucleotide substitution model such as HKY85 to describe the substitution process at the DNA level, with a genetic code matrix embedded on top of it. This genetic code matrix typically has three values, 1 for synonymous changes that involve a single nucleotide change, 0 for all changes that involve more than a single nucleotide change, and free parameter ω (dN/dS) for nonsynonymous changes that involve a single nucleotide change. This is motivated by the expectation that selective constraints on nucleotide changes that change the amino acid will be different from selective constraints on nucleotide changes that do not, leading to different rates. In the Goldman-Yang model, there are independent DNA process at each codon position, such that a different rate matrix is estimated for the 1st, 2nd, and 3rd codon positions (Goldman and Yang, 1994). In the Muse-Gaut model (Muse and Gaut, 1994), there is a single DNA level process that applies equivalently to all three positions, reflected in a common substitution matrix between them.

A second type of codon model also involves free parameters estimated directly from data, but stems from an attempt to model the underlying population genetics. In Halpern-Bruno style models (also called mutation-selection models), the probability of introducing a mutation to a population is reflected by the product of the mutation rate and the population size (Halpern and Bruno, 1998). For a mutation that is introduced, the fixation probability reflects the probability of going from frequency $1/N$ ($1/2N$ in a diploid population) to fixation. This second probability depends upon the population size and the selective coefficient for the change, which in linear space is $(f'/f) - 1$, where f' is the fitness of the new amino acid and f is the fitness of the original amino acid, sampled from a vector of 20 amino acid fitnesses (19 parameters).

The third class of models is a 64×64 (61×61 when stop codons are excluded) empirical model calculated in a similar manner to amino acid substitution models. An early instance of such a model that has been constructed comes from Schneider *et al.* (2005). This class of model explicitly contains averaged data on amino acid properties that is lacking from the ω -based models.

Recent work has enabled model selection across classes of models (including nucleotide, codon, and amino acid models), but has only included the first class of codon models in the set of models that are available for testing (ModelOMatic; Whelan *et al.* (2015)).

CAT Models

One class of models that is currently widely held as the state of the art for amino acid models is the CAT models (Lartillot and Philippe, 2004), based upon its ability to fit data well for the number of parameters. This model class includes a distribution of equilibrium frequencies across sites that describes the propensities for different amino acids to occur at different positions within a protein, bearing some similarity to a mixture of F81 models in protein state space. The number of categories is either defined a priori or by a Dirichlet distribution. To account for temporal heterogeneity at a site, due to epistasis (the non-independence of the evolutionary process at each site), the CAT-BP model was introduced that allows for class switching at a site (Blanquart and Lartillot, 2008).

Covariation Models

The models described so far (besides CAT-BP and some implementations of codon models) all assume that the same evolutionary process applies to all sites in an alignment on all lineages of a phylogenetic tree. While they can be applied as heterogeneous process models with discrete breaks in process at nodes of phylogenetic trees, a class of models called covariation models describes explicit rate shifting parameters (Miyamoto and Fitch, 1995). The simplest model, Tuffley-Steel, includes a parameter for shifting between a particular rate class and an invariant site (Tuffley and Steel, 1998). Galtier described a model where sites with different rate classes can shift between each other (Galtier and Jean-Marie, 2004). Roger generalized this as the General Covariation Model, with parameters to shift between rate classes and into and out of invariant states (Wang *et al.*, 2007). Overall, this modeling

Fig. 2 An overview of covarion models is shown. r_0 states on the left reflect temporally invariant states that are accessible from states with different rates in models that incorporate this (red arrows) “Tuffley-Steel” process. Blue arrows depict the shifts between states with different rates, shown as four distinct gamma categories here. The general covarion model allows both the red and blue arrow states to occur.

framework can be applied as a general Markov process framework for temporal heterogeneity at a site. **Fig. 2** shows a summary of the modeling framework, including transitions for a site between a rate category and invariant states as well as between rate categories. Covarion processes are expected to account for the role of epistasis in enabling temporal shifts in the evolutionary processes at individual sites.

Physicochemical Models of Substitution

An alternative to using empirical matrices to characterize amino acid substitution is to use metrics of the physical chemical distance between amino acid side chains. The Grantham matrix ([Grantham, 1974](#)), the most widely used of such matrices, is calculated as a normalized RMSD between side chain atomic composition, polarity, and volume. It is most commonly used to weight amino acid differences or in metrics that examine rates of radical and conservative amino acid changes based upon Grantham matrix values. It can be extended to use as a full Markov model for phylogenetic purposes as well.

Empirical Contact Models

Another alternative to a traditional substitution matrix is to use a contact potential matrix. [Miyazawa-Jernigan \(1985\)](#) is a matrix that reflects the average pairwise potential of two amino acids in contact at a given distance based upon a statistical analysis of protein structures (see **Fig. 3**). This treatment enables explicit consideration of protein structure, that is not treated in other models that have been discussed. It does not consider either angular or distance information between residues that can be important in characterizing energies of interaction. To use this matrix for substitution, the difference in the sum of contacts between the original and substituted amino acids in the protein structure is used to generate an expected energetic change in the folding energy. Assuming that the strongest selective pressures are reflected in the fraction folded of a molecule based upon this energy, the fitness difference (selective pressure) associated with a change is then calculated by placing a Boltzmann distribution in a function to calculate the probability of fixation of the change.

Bastolla has generated updated contact potential matrices and most recently, a mean field model for use in ancestral sequence reconstruction ([Arenas *et al.*, 2017](#)). [Robinson *et al.* \(2003\)](#) introduced an early codon model with structure dependencies and novel statistics to enable computation. [Kleinman *et al.* \(2010\)](#) and [Grahnen *et al.* \(2011\)](#) have generated fuller structure-aware models for amino acid substitution that include distance and angular terms, but these methods are slow and have not performed well in characterizing individual site probabilities of substitution in actual alignments when compared with the best performing models (e.g., CAT).

$$\Delta u_{i \rightarrow i'} = (u_{i'j} - u_{ij}) + (u_{i'k} - u_{ik})$$

Fig. 3 An overview of the use of a contact potential matrix for substitution is shown. Residues j and k interact with residue i . On mutation from i to i' , $\Delta u_{i \rightarrow i'}$ reflects the corresponding change in potential resulting from the two underlying physical interactions in the protein structure.

Conclusions and Future Directions

Markov models are widely used in biological sequence analysis, as described in the approaches to date. DNA models are fairly good approximations to underlying biological processes, particularly for neutrally evolving sites. One ongoing area of research with DNA models is their implementation as time heterogeneous models that can account for changes in base frequencies over time. Codon models come in two main varieties, those built with a genetic code model over a DNA model and those built as empirical codon models. As with amino acid models, codon models approximate the complexity of selection on protein sequences, structures, and functions (see [Chi and Liberles \(2016\)](#) for a recent discussion of this). An incomplete synthesis involves incorporating structural or advanced statistical techniques to build better models for proteins. Markov models of all of these varieties are an important trajectory in bioinformatics.

Introduction

Our understanding of biological patterns and processes is greatly improved by knowledge of evolutionary timescales. The inference of these timescales has traditionally been based on evidence from the fossil record, which provides an indication of when species diverged and when key biological innovations arose. Unfortunately, the fossil record is very incomplete for many branches of the Tree of Life. Groups such as bacteria and various invertebrates have left scant traces, despite the persistence of their lineages through many millions of years. Additionally, fossil evidence is usually unable to resolve the timing of very recent events, such as demographic changes occurring within species or the transmission of pathogens across their host populations (Arbogast *et al.*, 2002).

When the fossil record is uninformative about evolutionary and demographic timescales, we require temporal information from another source. The answer to this problem arrived in the 1960s when the idea of a 'molecular evolutionary clock' was proposed by Zuckerkandl and Pauling (1962, 1965). Molecular clocks describe the relationship between evolutionary rate and time, with the simplest clock model assuming that the rate of molecular evolution is constant across species. This allows us to use phylogenetic analyses of genetic data to estimate evolutionary and demographic timescales (Fig. 1). The most widely used forms of data for this purpose are nucleotide and amino acid sequences. To give estimates in terms of absolute time, however, molecular clocks need to be calibrated using independent evidence about the timing of one or more evolutionary divergences in the phylogeny.

Molecular clocks have been used to provide insights into a number of significant evolutionary events, ranging from human prehistory to the deep divergences among the kingdoms of life. They are now being applied to genome-scale data sets that comprise thousands of genes from dozens to hundreds of taxa (Tong *et al.*, 2016). For example, evolutionary timescales have been inferred using large data sets from birds (Jarvis *et al.*, 2014), flowering plants (Foster *et al.*, 2017), and insects (Misof *et al.*, 2014). The methods underpinning molecular-clock analyses continue to evolve, which is imperative if we are to make the most of the growing wealth of genomic data.

The objective of this article is to provide an overview of the molecular clock. First, we will present a brief history of the molecular-clock hypothesis and its early applications. Second, molecular-clock methods and models will be described, as will the challenges to their implementation. Following a case study on the origins of lobsters, we will discuss the role of molecular clocks in the genomic era.

Background

The Origins of the Molecular Clock

Zuckerkandl and Pauling (1962) were the first to propose the idea of a molecular clock. In their analysis of globin proteins, they assumed a constant evolutionary rate in order to estimate the timing of past gene duplications in vertebrates. They found 18 amino acid differences separating human and horse, and estimated the evolutionary rate of this protein by assuming that these two species split from each other 100–160 million years ago. This evolutionary rate was then extrapolated to the globin genes of other animals to show that humans and gorillas split from each other approximately 11 million years ago, and that different globin genes first diverged during the late Precambrian (Zuckerkandl and Pauling, 1962).

Fig. 1 Simple illustration of molecular dating. The phylogenetic tree depicts the evolutionary relationships among six primate species, inferred using genetic data from each species. Fossil evidence indicates that modern humans last shared a common ancestor with chimpanzees about 6.5 million years ago. This 'calibration' allows us to infer the rate of molecular evolution within the descendent branches (dashed lines). If this rate is assumed to remain constant throughout the tree (known as a 'strict molecular clock'), we can estimate the timing of all other divergence events.

Studies of other proteins throughout the 1960s provided further evidence of constant, clocklike evolution, leading [Zuckerlandl and Pauling \(1965\)](#) to put forward the term 'molecular evolutionary clock'. Promising to be a valuable tool in biological research, the power of the molecular clock was soon demonstrated when [Sarich and Wilson \(1967\)](#) inferred the evolutionary timescale of hominids and related primates.

The molecular-clock hypothesis relies on the idea that rates of molecular evolution, as seen in mutations in protein or DNA sequences over time, are relatively constant between lineages. The occurrence of mutations is often modelled as a Poisson process, reflecting the stochastic nature of the molecular clock. Although individual mutations do not occur at strictly regular intervals, the genetic difference between any two species will increase monotonically over time. If the evolutionary rate has been constant, then genetic divergence will be directly proportional to the time since the two species last shared a common ancestor. This relationship allows evolutionary timescales to be inferred from genetic data, provided that we know the rate of molecular evolution.

When initially proposed, the notion of a constant rate of molecular evolution created controversy. A number of researchers, including the prominent palaeontologist [Simpson \(1964\)](#), viewed the molecular clock with scepticism. It seemed implausible that a simple statistical model could describe a process as seemingly complex as that of molecular evolution. In the late 1960s, however, new ideas about molecular evolution would provide some support for the concept of a molecular clock.

Neutral and Nearly Neutral Theories of Molecular Evolution

Alongside the early criticisms of the molecular clock, there was growing evidence of high evolutionary rates in a range of proteins. This suggested that a substantial proportion of amino acid mutations have negligible impacts on fitness. In response to this evidence, [Kimura \(1968\)](#) proposed the neutral theory of molecular evolution. This theory states that many mutations do not have a measurable impact on the organism's fitness, so that their frequencies in the population vary stochastically by genetic drift rather than being driven by natural selection. These neutral mutations might represent the replacement of amino acids by other amino acids with similar biochemical properties. In protein-coding genes, some nucleotide mutations do not result in any changes to the encoded protein, so their effects on fitness are likely to be very small.

The neutral theory of molecular evolution predicts that evolutionary rates, measured on a per-generation basis, are constant across lineages ([Kimura, 1968](#)). However, generation lengths vary between species, meaning that we expect a generation-time effect: molecular evolution occurs more quickly per unit of time in species with shorter generations. For example, rodents express a higher rate of evolution than primates. Such generation-time effects have been identified in a broad range of organisms.

At the end of the 1960s, some studies found that the rate of protein evolution was independent of generation time. This contradicted the expectations of the neutral theory, leading [Ohta \(1972, 1973\)](#) to propose the nearly neutral theory of molecular evolution. In this model, most mutations are assumed to have a small effect on fitness. In contrast with the neutral theory, the nearly neutral theory gives a central role to the effect of population size. Natural selection is effective at removing harmful mutations in large populations, but the process of genetic drift dominates in small populations. However, there are more opportunities for mutations to arise in large populations. [Ohta \(1972\)](#) predicted that these two effects would offset each other, with the net effect being a constant evolutionary rate per unit of time across species.

Molecular Clocks in Practice

In the decades following the proposal of the molecular clock, genetic data have been used to estimate the evolutionary timescales of various parts of the Tree of Life. Among the most conspicuous studies were those of the deep divergences among metazoan phyla. The date estimates from these analyses pointed to a much longer timescale of evolution than indicated by the fossil record. In conflict with the idea of an explosive evolutionary radiation in the Cambrian period, the basal metazoan divergences were estimated to have occurred much deeper in the Precambrian (e.g., [Runnegar \(1982\)](#), [Bromham *et al.* \(1998\)](#)). These striking discrepancies between genetic and fossil-based estimates of evolutionary timescales led many to question the reliability of molecular clocks.

There has also been abundant evidence of rate variation across lineages, contradicting the simplistic assumption of clocklike evolution. These challenges to rate-homogeneous models have driven the development of 'relaxed' molecular clocks, the first of which appeared in the late 1990s. These clock models are able to relax the assumption of rate homogeneity among lineages ([Sanderson, 1997](#); [Thorne *et al.*, 1998](#)). There is now a wide range of relaxed-clock models, implemented in various statistical frameworks ([Ho and Duchêne, 2014](#)). Among the most commonly used in phylogenetic inference are those based on the Bayesian approach ([dos Reis *et al.*, 2016](#)).

Approaches

Molecular-Clock Methods

The molecular clock is typically used as part of a phylogenetic analysis, in a procedure known as molecular dating. This involves inferring the evolutionary relationships among a sample of taxa, along with the evolutionary rates and time durations of the branches of the phylogenetic tree. Molecular dating comprises several key steps ([Fig. 2](#)): (i) selecting a data set, (ii) identifying

Fig. 2 Major components of a molecular dating analysis. The user begins by assembling a genetic data set, identifying suitable calibrations for the molecular clock, and selecting a method of analysis. Statistical model selection should then be performed to identify the best-fitting models of substitution and rate variation. Following the analysis of the data, the results then need to be interpreted and placed into the appropriate biological and evolutionary context.

calibrations for the molecular clock, (iii) selecting an estimation method and a model of rate variation, and (iv) running the analysis.

Choosing a data set for analysis depends on the questions that are being addressed. In most cases, nucleotide sequences are used for molecular-clock analyses because of the relative ease of obtaining these data and because of their information content. Sequences should represent the diversity of the organisms being analysed and should be sufficiently long to enable precise estimation of the amount of evolutionary change. However, genetic markers vary in their utility for molecular dating. Evolution tends to occur very slowly in functionally important genes, making them useful genetic markers for studying deep evolutionary timescales. In contrast, analyses of recent events are most effective when rapidly evolving genes are used. In animals, the mitochondrial genome typically evolves much more rapidly than the nuclear genome (Brown *et al.*, 1979). This pattern is reversed in plants: nucleotide substitutions tend to occur more rapidly in the nuclear genome than in the mitochondrial and chloroplast genomes. Mutation rates in viral genomes are higher than those in animals and plants by several orders of magnitude. In any case, analysing multiple genetic markers is now commonplace, and genome-scale data sets are seeing increasing use in molecular-clock studies (Ho, 2014).

The process of selecting calibrations, estimation methods, and models of rate variation can be informed by statistical analysis, but still involves a large degree of uncertainty. A wide range of methods are available, and these appeal to various philosophies and differ in their strengths and weaknesses (Ho and Duchêne, 2014; dos Reis *et al.*, 2016). There are also many practical factors that need to be considered, especially when analysing large data sets that comprise many sequences and/or many taxa.

Calibrating the Molecular Clock

The most critical component of molecular-clock analysis is the process of calibration. If the rate of evolution is unknown, the molecular clock must be calibrated in order for evolutionary timescales to be estimated. This involves constraining the age of at least one node in the phylogeny, allowing the average rate of its descendent branches to be inferred. The remaining nodes in the tree can then be estimated by assuming some model of rate variation across branches.

Calibrations can be chosen according to evidence from the fossil record, geological events, or past climatic events. In practice, fossil calibrations are probably the most common (Hipsley and Müller, 2014). Provided that a fossil taxon can be assigned to a lineage in the phylogeny, its age can be used to place a minimum constraint on the age of its ancestor. However, minimum age constraints need to be combined with at least one maximum age constraint in the tree. Choosing an appropriate maximum age constraint for the tree is a difficult exercise, because it relies on the assumption that a particular lineage or group did not exist before a certain time. Various criteria have been put forward for choosing appropriate fossil calibrations for the molecular clock (Parham *et al.*, 2012; Sauquet *et al.*, 2012).

In Bayesian methods, calibrations are implemented by specifying the prior distributions of the relevant node ages. For example, a node-age prior can be specified in the form of a lognormal or gamma distribution. These calibration priors can allow various sources of uncertainty to be taken into account, including errors in radiometric dating and the probability of fossil preservation (Ho and Phillips, 2009). Nevertheless, the uncertainty in the fossil evidence is rarely modelled explicitly, and the fossils themselves are only used indirectly to inform the calibration priors.

Recent developments in calibration methods have aimed to incorporate fossil evidence more comprehensively. Total-evidence dating uses combined data sets comprising genetic data from extant species and morphological data from both extant and extinct species. The morphological data are used to infer the placement of the extinct species in the tree, and the ages of these species calibrate the clock by constraining the ages of their ancestral nodes (Ronquist *et al.*, 2012). This method removes the need to choose age constraints for nodes based on fossil evidence, by instead allowing the fossils to be included directly in the analysis. Nevertheless, the method has a number of problems that still need to be addressed (O'Reilly *et al.*, 2015). In this regard, a key area of research is the development of more realistic models of morphological evolution.

Geological events can also be used for calibration, provided that they can be tied to evolutionary divergence events among the sampled taxa (Ho *et al.*, 2015). These divergences can be caused by disruptions in the range of an ancestral species (vicariance), the formation of connections between previously isolated habitats (geodispersal), or dispersal across barriers and establishment of new populations (biological dispersal). Examples of these include evolutionary diversification associated with continental fragmentation or the colonization of newly formed islands (e.g., Fleischer *et al.* (1998)). The timing of these events can be estimated using radiometric dating methods. However, biogeographic calibrations are typically associated with large amounts of uncertainty and are sometimes regarded as unreliable (Kodandaramaiah, 2011).

In some cases, the ages of the sequences can act as calibrations (Rambaut, 2000). These tip-calibrations can be used when there has been enough time separating the sequences to allow an appreciable amount of genetic change to occur (Drummond *et al.*, 2003). This is the case for some data sets comprising virus sequences sampled over time, or that include ancient sequences that have been radiocarbon-dated.

In the absence of primary calibrating information, age constraints can be applied to nodes in the tree based on previous molecular estimates. This practice is deprecated by some researchers, given the uncertainties in molecular dating and the potential sensitivity of date estimates to various confounding factors. However, such an approach might be the only feasible option in analyses of taxa with a poor fossil history. If secondary calibrations are employed, their uncertainty should be taken into account explicitly (Graur and Martin, 2004); this is readily done in Bayesian phylogenetic methods.

Models of Rate Variation

Evolutionary rates vary in a number of important ways, placing great importance on the act of selecting an appropriate clock model. Clock models describe how rates are expected to vary across branches in the tree and across genes in the data set. A simple way of accounting for different rates across genes is to assign a relative rate parameter to each gene. Accounting for rate variation across branches is more difficult, and various models have been developed for this purpose. One convenient way of classifying these models is to consider the number of distinct rates (k) that they allow in comparison with the number of branches (n) (Fig. 3; Ho and Duchêne, 2014).

The simplest model of rate variation is the strict clock, which assumes that all branches share the same rate ($k=1$). This model is often rejected in practice, with significant evidence of rate variation across branches being found for many data sets. However, the strict clock might be valid when analysing sequences from conspecific individuals or closely related species. It is also a useful null model when testing for evolutionary rate heterogeneity.

Local-clock models assume that there are several distinct evolutionary rates across the tree ($1 < k < n$). These models might be appropriate when there is reason to believe that some branches in the tree are likely to share an evolutionary rate that is different from those along other branches (Yoder and Yang, 2000). Some local-clock models require the tree topology to be fixed and for distinct rates to be assigned to pre-defined sets of branches, but the Bayesian random local clock allows all of these to be inferred jointly (Drummond and Suchard, 2010).

Variants of local-clock models allow the branches sharing the same rate to be distributed throughout the tree, rather than necessarily being closely related to each other. These are sometimes known as 'discrete clocks' (Fourment and Holmes, 2014). Discrete clocks have been implemented in a range of statistical frameworks, including likelihood and Bayesian methods (e.g., Heath *et al.* (2012)).

The assumptions of the molecular clock can be relaxed even further, to allow a distinct rate of evolution along each branch in the tree ($k=n$). In order for these rates to be identifiable, there must be some form of constraint on their variation. The earliest relaxed-clock models assumed that rates evolve gradually throughout the tree, such that rates are autocorrelated (Sanderson, 1997, 2002; Thorne *et al.*, 1998). In these models, evolutionary rates are assumed to be similar between adjacent branches in the tree. There are implementations of autocorrelated-rate models in likelihood methods, but most of the recent developments have occurred in a Bayesian framework.

In a second class of relaxed-clock models, known as uncorrelated relaxed clocks, the branch rates are drawn independently from an underlying probability distribution (Drummond *et al.*, 2006; Rannala and Yang, 2007). Thus, there is no prior assumption that the rates along adjacent branches are similar to each other. A mixed relaxed clock can incorporate both autocorrelated and uncorrelated models by partitioning the rate variation between them (Lartillot *et al.*, 2016).

Fig. 3 The three major classes of clock model, based on the number of distinct rates that are allowed across branches in the phylogenetic tree. Branch shading indicates the relative evolutionary rate. (a) Strict clock, in which a single rate is shared by all branches. (b) Local clock, in which the number of rates is much smaller than the number of branches. Rates are typically shared between adjacent branches in the tree. In this example, there are three different rates across the tree. (c) Relaxed clock, which allows a distinct evolutionary rate for each branch in the tree.

Challenges

The molecular clock has faced a variety of challenges over the past few decades, and some of the most prominent estimates of evolutionary timescales have been controversial. The most important criticisms of molecular clocks have concerned the impacts of evolutionary rate variation across timescales, along with the use of calibrations.

The notion of constant evolutionary rates has been subject to numerous criticisms. It is now widely accepted that rates of evolution vary substantially across the Tree of Life. This rate variation is due to biological factors such as differences in population size, generation length, and natural selection, as well as abiotic factors such as exposure to ultraviolet radiation (Bromham, 2009).

Part of the controversy surrounding rate variation is the use of ‘universal’ molecular clocks, which assume a constant rate among species within a broad taxonomic group. For example, there is widespread use of universal clocks in studies of arthropods, birds, and mammals, whereby an evolutionary rate of 1% per million years is assumed for mitochondrial DNA (e.g., Weir and Schluter, 2008). However, the reliability of assuming a standard rate across an entire taxonomic group has been regularly challenged (e.g., Nabholz *et al.*, 2008; Nguyen and Ho, 2016). Given the abundant evidence that even closely related species can show substantial rate variation, the application of universal clocks can produce very misleading estimates of evolutionary timescales. Nevertheless, these clocks are still commonly used because there is often no other information about rates at hand.

The outcome of a molecular-clock analysis is substantially influenced by the choice of calibrations, and this has also been a major criticism of molecular dating. If calibrations are incorrectly modelled, the resulting date estimates can be highly inaccurate. When fossil calibrations are used, the selection of fossils can be subjective and their placement needs to be adequately justified. In Bayesian molecular dating, a further problem is that the calibration priors can interact with each other, producing joint priors on node times that no longer represent the fossil evidence used to specify the calibrations individually (Heled and Drummond, 2012; Warnock *et al.*, 2012).

The uncertainty in fossil calibrations can be modelled and quantified in various ways (e.g., Marshall (2008), Wilkinson *et al.* (2011)), and recently developed methods allow fossil data to be incorporated in a more satisfying manner. For example, total-evidence dating and the fossilized birth-death process allow fossil taxa to be treated as part of the evolutionary process (Heath *et al.*, 2014; Ronquist *et al.*, 2016). Although some aspects of calibration methodology remain debated, best practice involves using multiple calibrations for molecular dating.

Fig. 4 Phylogeny and evolutionary timescale of lobster-like decapod crustaceans, inferred using a Bayesian phylogenetic analysis of molecular and morphological data by Bracken-Grissom *et al.* (2014). 'Outgroups' indicate groups of crustaceans that do not belong to the four infraorders of lobster-like decapods. Filled circles at internal nodes indicate the placement of fossil calibrations. Line drawings of animals show representatives of the four infraorders indicated in bold, and have been traced from images presented in the study by Bracken-Grissom *et al.*, 2014. The emergence of lobsters: phylogenetic relationships, morphological evolution and divergence time comparisons of an ancient group (Decapoda: Achelata, Astacidea, Glypheidea, Polychelida). *Systematic Biology* 63, 457–479.

Case Study: The Emergence of Lobsters

Lobsters are a morphologically diverse group of crustaceans belonging to the order Decapoda. They are economically and culturally important, representing a key resource for many fisheries throughout the world. Their exoskeletons increase their probability of preservation, meaning that they have a rich fossil record extending back approximately 350 million years. This record provides a unique opportunity to study the origins and diversification of major lineages within the group.

Bracken-Grissom *et al.* (2014) analysed data from 173 species to infer the phylogeny of lobster-like decapods. This sampling included 94% of extant genera and allowed the authors to resolve contentious relationships among and within groups (Fig. 4). Using a total-evidence approach, the authors analysed a combination of 190 morphological characters, three nuclear genes (18S, 28S, and H3), and three mitochondrial genes (16S, 12S, and CO1). The genetic markers included both fast- and slow-evolving genes, allowing various relationships to be resolved throughout the tree.

For each of the genes in the data set, Bracken-Grissom *et al.* (2014) identified the best-fitting model of nucleotide substitution. By inferring the tree from each gene individually, the authors checked for congruence in the phylogenetic signal across the six genes. Both maximum-likelihood and Bayesian phylogenetic methods were used to infer the evolutionary relationships among taxa. A relaxed molecular clock was used to account for rate variation across lineages. In one analysis, the clock was calibrated using the ages of 28 relevant fossils. These calibrations were implemented as exponential or uniform prior distributions for the ages of the corresponding nodes in the tree. In a second analysis, calibrations were based on a model of fossilization, speciation, and recovery (Wilkinson and Tavaré, 2009). The two approaches to calibration led to very similar sets of divergence-time estimates.

Bracken-Grissom *et al.* (2014) found that decapods arose in the Ordovician, with the most recent common ancestor of extant genera appearing in the Cretaceous. During the Jurassic, the infraorder Achelata rapidly diversified, coinciding with the early break-up of Pangaea. Southern and Northern Hemisphere crayfish were estimated to have diverged approximately 261 million years ago. In addition to these date estimates, Bracken-Grissom *et al.* (2014) provided a range of useful guidelines for incorporating fossil calibrations in molecular-clock studies.

Future Directions

Over the past decade, there have been substantial advances in DNA-sequencing technologies, leading to a dramatic increase in the data available for molecular dating. As a consequence, molecular-clock methods have had to evolve to deal with large data sets (Ho, 2014). Most of these data sets comprise either large numbers of taxa or large numbers of genes, but there is a growing trend towards genome-scale data sets that include many dozens of taxa (e.g., Jarvis *et al.* (2014), Misof *et al.* (2014)). These data sets can contain significant amounts of complex rate variation and can pose difficult computational challenges. The growing availability of genome-scale data sets has spurred the development of methods that can cope with large data sets, either by improved distribution of computational load or by relying on approximations of likelihood calculations (e.g., dos Reis and Yang (2011)). Nevertheless, current Bayesian phylogenetic methods are not capable of analysing data sets comprising large numbers of taxa and genes.

Molecular dating using genome-scale data sets must deal with the problem of incongruent gene trees. When the divergences between lineages have occurred in rapid succession, there is an increased probability of the phylogenetic signal being heterogeneous across the genome. In particular, the evolutionary histories of individual genes might not match the relationships among

the species, in a phenomenon known as incomplete lineage sorting. This problem has not been satisfactorily addressed in molecular dating, but it remains an active area of research.

The growing access to genome-scale data sets raises an important question: does the precision of molecular dating improve with the amount of data? Various investigations have revealed that even with infinite data, the error in Bayesian date estimates depends on the uncertainty in the calibrations (dos Reis and Yang (2013)). Further improvements in estimates of evolutionary timescales will rely on the discovery of informative fossils and the development of better methods for integrating fossil and molecular data.

Closing Remarks

The molecular clock has been used in thousands of scientific studies, with no signs of declining relevance in the genomic era. Throughout its long history, the molecular clock has undergone substantial evolution and has proven to be a valuable tool for estimating evolutionary timescales. Applications of the molecular clock have been widespread, ranging from macroevolutionary studies of speciation and extinction to monitoring the evolutionary dynamics of modern-day pathogens.

Molecular-clock approaches have evolved from the assumption of constant evolutionary rates to the current models of rate variation across lineages. There has been an increase in efforts to incorporate fossil data into molecular dating, through total-evidence dating and the fossilized birth-death process. By taking advantage of the large amounts of genomic data being generated, molecular-clock methods will continue to play an important role in understanding the timescale of the Tree of Life.

Biographical Sketch

Cara Van Der Wal is a marine evolutionary biologist interested in molecular clocks, phylogenetics, computational biology, systematics, and population genetics. She is a PhD candidate at the University of Sydney and the Australian Museum. Prior to commencing her PhD, Cara studied marine biology at the University of Technology Sydney and did research on stomatopod crustaceans at the University of Sydney.

Simon Ho is a Professor of Molecular Evolution at the University of Sydney, where he leads the Molecular Ecology, Evolution, and Phylogenetics research group. He is a computational evolutionary biologist interested in molecular clocks, evolutionary rates, phylogenetic methods, genomic evolution, and ancient DNA. He previously worked at the Australian National University and the University of Oxford, after being awarded his DPhil from the University of Oxford in 2006.

Phylogenetic Tree Rooting

Glossary

Additive tree A tree in which the branch lengths are scaled according to time or the amount of evolutionary change.

Clade A group of terminal nodes (OTUs) that share a common ancestral node (HTU).

HTU Hypothetical Taxonomic Unit. An internal node of a phylogenetic tree.

Molecular Clock The prediction of The Neutral Theory that, if most fixed changes are the result of neutral mutations, molecular evolution will occur at a reasonably regular “clock-like” rate, determined primarily by the neutral mutation rate.

Monophyletic A trait (physical or genetic) that occurs within a single clade on a phylogenetic tree and thus can be explained by a single evolutionary event.

OTU Operational Taxonomic Unit. A sequence or organism used as the terminal nodes of a phylogenetic tree.

Parsimony The simplest explanation for an observation. The smallest number of changes needed to explain the data.

Topology The branching order of a phylogenetic tree.

Ultrametric Additive tree where all root-to-tip paths have an equal summed branch length.

Introduction: Phylogenetic Trees and the Role of the Root

A **phylogenetic tree** is a graphical representation of the evolutionary relationships between biological entities (Box 1). Phylogenetic trees can be used to model the relationships of organisms (“species trees”) or, in the case of molecular phylogenetics, biological sequences (“gene trees” or “protein trees”). The methods differ in their details but the essence is the same, in which attempts are made to generate a branching structure that recapitulates the true biological relationships of the organisms or sequences in question. Because molecular phylogenetics is (a) more common (thanks to the ease of generating genetic data), and (b) inherently quantitative (due to the digital nature of the data itself and the quantitative nature of substitutional models), the rest of this chapter will be targeted at molecular phylogenetics. Unless otherwise stated, what is true for molecular phylogenies will generally also apply to species trees inferred from other types of data (e.g. morphology).

Phylogenetic trees are a special kind of dendrogram (or hierarchical clustering) in which the internal nodes are inferred to represent actual biological entities, namely common evolutionary ancestors of two or more leaves. The **role of the root** is to add direction to these relationships and clearly distinguish which internal nodes are ancestral to which tips (Fig. 1(a)). Relationships between sequences are captured by the **topology**, which is the branching order (Fig. 1(b)) and, where appropriate, **branch lengths** that indicate the amount of evolutionary change (or time) between nodes (Fig. 2). Note that **topology only** trees (such as Figs. 1(a) and 2(a)) do not have meaningful branch lengths, which limits the rooting options (discussed below).

Phylogenetic methods can broadly be divided into three classes:

1. **Parsimony methods** seeks to minimize the number of evolutionary events required to explain the data. Parsimony methods are often biologically meaningful but only use a subset of “informative” data that can be used to split sequences into two or more groups of two or more sequences.
2. **Distance methods** convert pairwise comparisons of sequences into a distance matrix and then cluster sequences based on proximity or use an algorithm to try to minimize overall branch lengths. Distance methods use all the data but add a layer of abstraction between the actual biology and the inferred phylogeny. They tend to be very computationally efficient and thus are popular choices for non-experts.
3. **Model-based methods** (generally Maximum Likelihood or Bayesian methods) use an explicit evolutionary model to try to infer the phylogenetic tree that best fits the data. In principle, these methods are best as they are both biologically meaningful *and* use all the data. The downside is that they are dependent on the selected evolutionary model and can be very computationally intensive.

Rooting is largely independent of the method used to infer the phylogeny. Here, the primary consideration is whether branches have lengths, or only the topology (branching order) is established (Fig. 2).

In **additive trees**, branch lengths represent evolutionary change. For species trees, this is often an estimation of literal times of divergence. For sequence trees, branch lengths generally represent evolutionary change more directly, in terms of substitutions per site. Converting non-sequence data into a scaling numerical value with a reasonably constant rate through time is very challenging. For this reason, trees based on morphology tend to use parsimony approaches and often do not have branch lengths. Where branch lengths (and roots) are set, it is often using independent data, such as fossils. Where fossil evidence is incorporated, it is possible to have actual historical samples in the tree. This is quite different from molecular phylogenetics where, except in very rare cases (e.g. frozen viral samples), the tree is wholly inferred from contemporary data.

Box 1 Trees as graphs

Phylogenetic trees are a special case of what is known as a graph, in which a series of **nodes** are joined by **edges**, known as **branches**. Nodes are split into terminal nodes (or “leaves” to keep with the tree analogy), also known as **Operational Taxonomic Units (OTUs)** and internal nodes, also known as **Hypothetical Taxonomic Units (HTUs)**; OTUs are generally the data on which the phylogenetic method operates, whereas HTUs are the hypothetical ancestors inferred by the method.

Unrooted trees (top figure) are “undirected graphs” in which the relationship between two connected nodes is symmetrical. Adding a **root** (bottom figure) adds directionality to the graph, such that each branch has an **ancestral node** closer to the root and a **descendant node** closer to the tips. Internal nodes now represent the **Last Common Ancestor (LCA)** of a **clade** of terminal nodes.

This chapter deals with strictly **bifurcating** (or **binary**) trees in which each HTU is connected to three branches (see Section “Midpoint Rooting”). In the case of rooted trees, this corresponds to one ancestral and two descendant branches.

Unless a **molecular clock** is assumed, substitution rates can differ throughout the tree. Many phylogenetic methods are vulnerable to large rate variations and, whilst they can compensate for an extent of variation, confidence in the phylogeny produced generally decreases as rate variation increases (see Section “Resolving Monophyly and Homoplasy”).

Rooting and Evolutionary Change

Rooting a tree adds an additional internal “node” (or HTU) to a tree, which indicates the **last common ancestor** of everything in the tree (**Box 1**). In doing so, the tree is given *direction*. In addition to inferring the relative relationships of our species/sequences based on the topology, we can now look at directions of change. One key thing to remember is that placing a root does not actually change the amount of evolutionary change in the tree. Rooting a tree on a branch simply partitions up the evolutionary changes attributed to that branch into the two post-root branches (**Fig. 3**). The critical difference is that evolutionary change now has an explicit **ancestral state** and **derived state** (**Fig. 1**) (see Section “Ancestral Sequence Prediction”).

Multifurcating Trees

For simplicity, this chapter is dealing with strictly **bifurcating** or **binary trees**, in which each internal node has one ancestral branch and two descendant branches, for a total of three branches (**Box 1**). Trees do not need to be strictly bifurcating and a node can have

Fig. 1 Tree rooting and topology. The same phylogenetic tree of five sequences A-E with different representations. (a) Hypothetical nodes F-H represent inferred ancestors but in an unrooted tree (left) the relationship between those ancestors and other nodes is unknown. Rooting the tree (right) does not change the topology (branching order) but adds an additional ancestral node that gives directionality. In the unrooted tree, node H could be the common ancestor of (AB)E, (CD)E or (AB)(CD). In the rooted tree, node H is unambiguously the common ancestor of (CD)E. Sometimes a tree appears to be rooted but has no explicit root node marked (center). Unless otherwise stated, it is safest to assume that such a tree is unrooted. (b) Evolutionary relationships are represented by the tree topology, i.e. the branching order. This is independent of the way that branches are represented, or the vertical arrangement of terminal nodes. Despite different vertical arrangements and styles, all three trees have the same topology.

Fig. 2 Branch lengths and molecular clock. When looking at a rooted phylogenetic tree, the spacing between nodes and the root can be used to identify whether branch lengths are being shown and, if so, whether a molecular clock is in operation. (a) A topology only tree is ultrametric (all terminal nodes are the same distance from the root) and its internal nodes are typically evenly spaced at regular intervals as branches join, starting closest to the tip. (Note: vertical spacing in this representation has no meaning.) (b) If the tree is ultrametric but internal nodes are not regularly spaced then branch lengths are being used in the context of a molecular clock (a constant rate of evolution). This is usually means it is an assumption of the phylogenetic inference method but it *could* also reflect empirically clock-like evolution. Such a tree is inherently midpoint-rooted. (c) If neither terminal nor internal nodes show regular spacing, branch lengths are being used and no (universal) molecular clock is assumed. In this example, midpoint rooting is used.

more than two descendant branches. This is known as **multifurcation**. This could be a genuine biological phenomenon – a single ancestral population or sequence may radiate into more than two distinct lineages in parallel. Alternatively, it could simply represent a lack of confidence in tree topology; low confidence branches may be collapsed to zero length to explicitly acknowledge

Fig. 3 Midpoint rooting. (a) Midpoint rooting starts with an unrooted tree with branch lengths. (b) Each pairwise tip-to-tip distance is calculated (only three shown) and the longest distance, L , selected to determine the root placement. The root is placed on this longest tip-to-tip path, equidistant from the two tips. (c) The evolutionary change along the rooted branches, d , is partitioned between the two new post-root branches such that $d_1 + d_2 = d$. (d) In the final tree, the two tips from the longest path, A and E, are furthest and equidistant from the root.

the lack of certainty about the branching order in that part of the tree. Unless otherwise stated, methods and considerations for rooting binary trees will also apply to multifurcating trees. (Multifurcation can be represented as a series of bifurcating branches of zero length).

Phylogenetic networks

Evolution is not always a neatly bifurcating process. Sexual reproduction, recombination and horizontal gene transfer can generate scenarios in which a given OTU has multiple ancestral HTUs. Traditional phylogenetic methods adopt a “winner takes all” approach to ancestry and it is up to the user to pre-partition the data where mixed ancestry may be an issue. **Phylogenetic network** methods will explicitly model mixed ancestry in addition to non-binary divergence. As with simpler multifurcation of descendants, rooting methods and considerations are broadly the same for a phylogenetic network and these will not be considered further in this chapter.

Rooting Methods

To correctly interpret a rooted tree, it is important to understand the assumptions and limitations of the rooting method used (see also Section “Why root a phylogenetic tree?”). There are a few different rooting methods, depending on the available data and reason for rooting (see Section “Inferring Rooting Methods”). These will be briefly summarized in this section.

Random Rooting

The simplest method for rooting a tree is to place the root on a random branch. This is clearly not a biologically meaningful rooting but repeating the process multiple times can be useful for establishing how robust the ultimate conclusions of a study are to incorrect rooting. In its simplest form, topology alone is considered. Alternatively, branches could be weighted by length, so that the root was more likely to fall in a long branch.

Midpoint Rooting

The easiest biologically meaningful rooting method is **midpoint rooting** (Fig. 3). Midpoint rooting needs an additive tree (i.e. scaled branch lengths, Fig. 2) and makes the explicit assumption that there are no major deviations in evolutionary rates (see Section “Resolving Monophyly and Homoplasy”) and that sequences are evolving in a reasonably “clock-like” fashion. Under this model, it follows that the root will be equidistant from the most divergent pair of sequences in the tree: if rates are reasonably

constant, the reason they are the most diverged is because they have had the longest period of independent evolution since splitting.

Midpoint rooting works by first establishing all the tip-to-tip distances by summing up the branch lengths of the shortest distance between two tips. The root is then placed in the midpoint of the longest tip-to-tip path (Fig. 3). If there are multiple equally-long paths, one is chosen at random, as they will all share an identical midpoint. **Ultrametric trees** (Fig. 2(b)) represent a special case of midpoint rooting where the evolutionary rate is constant throughout the tree and thus all tips end up equidistant from the root.

Midpoint rooting is attractive because it does not rely on any prior knowledge and can be calculated simply from the tree itself. However, the explicit assumption of constant evolutionary rates makes it quite unreliable in many real scenarios. It is advisable to look at how “clock-like” a tree appears, i.e. how much spread there is in root-to-tip distances following midpoint rooting (Fig. 2(c)), before deciding whether to trust midpoint rooting.

Rate-adjusted midpoint rooting

There are two main considerations for evolutionary rates:

1. The selective constraint of the sequence in that lineage.
2. The mutation rate of the sequence in that lineage, which is affected by generation time and the number of germline cell divisions per generation.

In principle, rate variations between branches can be modelled (as part of a model-based phylogenetic method) and the branch lengths normalized for different rates to convert them into evolutionary time. The tree could then be midpoint rooted based on rate-corrected branch lengths. However, this is often done by imposing a known species tree onto the gene tree to establish the branch-specific rates, which is essentially a form of outgroup rooting (see Section “Long Branch Artifacts”).

Outgroup Rooting

Outgroup rooting is the generally considered to be the Gold Standard of tree rooting. Here, prior knowledge is used to manually identify the ancestral branch in the tree. This is done by identifying a **clade** that is known to have branched off first from the rest of the tree, and then placing the root on the branch leading to that clade (Fig. 4). Often, the outgroup clade is a single OTU.

Selecting an outgroup

Selecting outgroup sequences is not always easy. As with all knowledge-based methods, outgroup rooting is only as good as the knowledge used. It will also make some explicit assumptions of the data, e.g. that all the sequences in the tree are orthologues (related by speciation). If a tree accidentally includes some paralogues (homologous sequences derived from duplication events),

Fig. 4 Outgroup rooting. (a) Outgroup rooting identifies the OTU or clade known to have diverged first from the rest of the tree. In this case, the marsupial kangaroo diverged from the four placental mammals. (b) The root is placed at an arbitrary point on the branch leading to the outgroup. Typically, this is done to minimize the difference in the root-to-tip distances. Unlike midpoint rooting, the two most divergent tips will not necessarily be equidistant from the root. (c) In this example, the rodent lineage is evolving faster than the rest of the tree, which would result in an incorrect midpoint rooting in which primates and marsupials share a common ancestor since their divergence from rodents.

Fig. 5 Parologue rooting artefacts. (a) True topology-only tree of a gene family with two genes A and B in five mammalian species. The root of the tree is a gene duplication event (star). Other nodes (filled circles) are speciation events. Genes related by duplication are paralogues. Genes related by speciation are orthologues. Missing data for subsequent trees is marked in red. (b) The true topology-only tree without the missing data from the original tree. Orthologues still form monophyletic clades and the root is a duplication event. (c) Using kangaroo as an outgroup but ignoring the paralogous nature of some of the sequences incorrectly roots the reduced tree and produces a confusing topology in which primates are non-monophyletic.

this assumption would be violated and the outgroup rooting could possibly go wrong (Fig. 5). Single, distant OTUs are more likely to be incorrectly placed in a tree, so it is usually better practice to root on an outgroup clade rather than a single sequence.

Using gene duplications as an outgroup

Although incorrect classification of proteins as orthologues or paralogues can lead to rooting issues (Fig. 5), known relationships between different members of a gene family can be used for outgroup rooting in the absence of known taxonomic relationships. In Fig. 5(a), for example, the duplication node can be used to root the tree. In effect, gene A is acting as an outgroup for gene B and vice versa. This can be useful even when one subfamily is poorly sampled, e.g. Human B could be used to outgroup root the entire Gene A clade.

Adding outgroups

Often, there is no obvious outgroup in the set of sequences or species from which you have made your phylogeny. (Indeed, establishing the nature of relationships is often the reason for making a phylogeny from these data.) In these cases, it is useful to add one or more additional sequences from known outgroups and then use these to root the tree. For example, when generating a phylogeny of placental mammalian species or sequences, one might add one or more marsupials to root the tree (e.g. Fig. 4). Alternatively, one can add paralogous sequences as described above (see Section “Using gene duplications as an outgroup”).

Unrooting and Re-Rooting Trees

Unrooting and re-rooting a tree is very simple. The two post-root branches are simply stuck together to (re)generate an unrooted tree (e.g. converting Fig. 3(d) to (c)). The new root can then be placed using any of the standard methods.

Recognizing Rooted Trees (and other Tree Attributes)

Correct interpretation of a phylogenetic tree relies on understanding the method used for rooting. Unfortunately, this information is not always provided. Fortunately, different tree attributes and rooting methods leave typical signs that can be used to identify the rooting method with reasonable confidence. If not possible, the safest course of action is probably to re-root the tree yourself (see Section “Unrooting and Re-Rooting Trees”). (Of course, once identified, you might not agree with the method used and want to re-root anyway).

Recognizing an Unrooted Tree

The easiest rooting method to recognize is where no rooting has been applied and the tree is in a radiation representation (Fig. 1(a), left). Sometimes unrooted trees are still drawn in a traditional “square branch” configuration (Fig. 1(a), center) even though

there is no actual root. This is most common – and hardest to spot – when only the tree topology is shown (Fig. 2(a)) but is sometimes the default output for phylogenetics programs. Ideally, a rooted tree will have an actual root node and/or branch shown (Fig. 1(a), right) but this is not always the case and so trees that look rooted but lack a root are inherently ambiguous. Displaying branch lengths will often make it clear whether such a tree has been rooted; any major disparity between the root-tip distances each side of the root should be a cause for concern. If in doubt, explicitly unroot or re-root the tree (see Section “Unrooting and Re-Rooting Trees”), depending on your needs.

Inferring Rooting Methods

When interpreting a rooted phylogenetic tree, there are five basic attributes that one should look for:

1. **Topology.** This is the basic shape of the tree, e.g. its branching pattern (Fig. 1). All phylogenetic trees have a topology and it is the only attribute that one can guarantee. Topology-only trees are recognized by the uniformity of the branching pattern (Fig. 2(a)).
2. **Branch lengths.** “Additive” trees have evolutionary change information encoded in their branches, giving different branches different lengths. Additive trees can be recognized by the fact that (except for rare situations) the internal nodes are no longer spaced evenly and “line up” (Fig. 2). This is a pre-requisite for midpoint rooting (see Section “Inferring Rooting Methods”).
3. **Molecular clock.** Most phylogenetics methods perform best when evolutionary rates are constant. Some methods go as far as to enforce this, producing what is known as an ultrametric tree. In this case, all leaves are equidistant from the root even though the internal nodes are not evenly spaced (Fig. 2(b)). If no molecular clock is imposed, different leaves will be different distances from the root (Fig. 2(c)).
4. **Midpoint rooting.** Even in the absence of other knowledge, it is possible to assess whether an additive tree is consistent with midpoint rooting. If it is then the longest root-to-leaf distance will be the same for each “side” of the tree (i.e. for each of the two descendant clades that split at the root itself) (Figs. 3(d) and 4(c)). On the other hand, if one side of the tree sticks out further than the other, midpoint rooting has not been used (Fig. 4(b)). In this case, the assumption is usually that outgroup rooting has been used but this can only be confirmed using independent knowledge. Note that for reliable trees, midpoint rooting and outgroup rooting will give the same root; consistency with midpoint rooting does not therefore rule out the use of outgroup rooting.
5. **Branch confidence.** Rooting on a particular branch can only ever be as confident as the branch itself. Methods of assessing branch confidence (typically bootstrapping or probability estimates) are beyond the scope of this chapter but will be recorded on a tree in the form of numbers associated with each branch. If the rooted branch has low support, the root itself should be considered uncertain. (Note that in most cases, the confidence estimates are made on the unrooted tree and so both descendant branches from the root will have the same confidence score.) Where confidence values are absent, branch lengths can be used as a proxy. (Note: if some scores are given and not others, missing values normally indicate low confidence.) Usually, longer branches will be more robustly supported by the data; the reason the branch is long is that a lot of data supports that division of the tree. This makes rooting particularly uncertain in scenarios of rapid early radiation, where deep branches are short. Neither branch confidence nor branch length is outright confirmation that the root (or even the topology) is correct; a phylogenetic method or alignment error might be consistently biased into producing the wrong tree. However, a low confidence and/or very short rooting branch should always make one wary of root placement. In principle, one can apply the same confidence methods to the root itself, e.g. midpoint rooting every bootstrap tree to establish how many times the root ends up in the same place. In practice, this is rarely done.

Long Branch Artifacts

Phylogenetics methods work best when:

1. Evolutionary rates are reasonably constant across the whole tree.
2. Sampling of OTUs is reasonably uniform so that there is enough data to determine relationships but not so many differences that they begin to get masked by “multiple hits” (where the same nucleotide or amino acid undergoes several substitutions *on the same branch*, masking the earlier changes).

Where sequences violate these conditions, and have a lot of divergence relative to all the other OTUs, methods can get misled and interpret an increased evolutionary rate as an increased time of divergence. Distance methods are particularly prone to this issue but Maximum Parsimony (and even likelihood methods) can also struggle when substitutions are getting saturated in rapidly evolving lineages.

For distance methods, very long branches tend to migrate towards the midpoint root of the tree because the other OTUs cluster first. This can result in both an incorrect (but sometimes highly supported) basal placement of those branches but also an incorrect rooting if midpoint rooting is used.

For Maximum Parsimony and model-based methods, the problem is subtler. Large numbers of substitutions increase the chance of randomly shared substitutions. If these begin to exceed the genuine shared substitutions of these sequences with their more slowly evolving neighbors, the rapidly evolving lineages can begin to cluster together in a phenomenon known as “long branch attraction”. Again, midpoint rooting will inherently tend to put the attracted clade near the root as the long branch lengths will also make them more likely to be part of the longest tip-to-tip path (Fig. 3).

Unfortunately, outgroup rooting is often performed by selecting a single sequence known to be more distantly related to all other OTUs. Assuming reasonably constant evolutionary rates, rooting on this outgroup will match midpoint rooting. This is a good thing but can be visually indistinguishable from a scenario where a single rapidly-evolving lineage has migrated to the root. This emphasizes the need to document the rooting method used. The outgroup might also “attract” other rapidly evolving sequences, which share sequence variants by chance. Where possible, outgroup rooting should be done using multiple sequences to produce a more “balanced” tree and avoid this issue.

Why Root a Phylogenetic Tree?

Most phylogenetic methods are inherently undirected. This enables the user to understand the hierarchical relationships between sequences or species but does not reveal (or predict) the ancestral state. The first question when considering the rooting of a phylogenetic tree is whether one needs to root the tree at all. Often this is not required for an analysis. This depends on how important it is to infer the direction of change (see Section “Random Rooting”, Fig. 1).

Phylogenetic trees are often generated to provide context for certain species or sequences. In this case, we are primarily interested in which clade contains our query sequence. This is often obvious from an unrooted tree, in which case it might be considered safer not to try to establish a root. For example, in Fig. 4, mouse and rat are clearly most closely related, wherever the root is placed. Likewise, when trying to identify an unknown gene, its phylogenetic position within a clade might be enough to predict its identity, independent of strict ancestry: a complete unrooted version of Fig. 5(a) would suffice to clearly identify which mouse sequence was Gene A and which was Gene B. (Things might be less clear for the kangaroo sequences).

Ancestry becomes important when we are interested in *how* a trait evolved and want to know when it appeared. Alternatively, perhaps we know a trait appeared at a certain time and want to see what sequence changes correlate with its appearance. As with the example above, sometimes it is not actually necessary to *accurately* root the tree to get the ancestry information that one needs.

Ultrametric Phylogenetic Methods

One trivial reason to root a tree is that the chosen phylogenetic method inherently produces a rooted tree. As previously discussed, “Ultrametric” phylogenetic methods (e.g. Unweighted Pair Group Method with Arithmetic mean (UPGMA)) explicitly assume a constant rate of evolution across all branches. As such, the tree root is set as part of the phylogenetic reconstruction itself at the point where the last pair of groups are joined. In Ultrametric trees, all terminal nodes (OTUs) are equidistant from the root (Fig. 2(a) and (b)). Ultrametric tree rooting is therefore a special case of midpoint rooting where there are multiple longest tip-to-tip paths.

Ancestral Sequence Prediction

One of the main reasons for wanting to know the direction of branching is to establish the direction and timing of evolutionary change (Fig. 1). Note that it can be very challenging to correctly allocate the ancestral state of the root itself when there is disagreement between the two post-root nodes (Fig. 6). In general, the ancestral node will tend to converge on the node with the shortest branch length because each substitution is more likely to occur on the longer branch. This can lead to the slightly paradoxical situation where a non-zero-length branch has zero substitutions assigned to it. This, in turn, highlights some of the difficulties in interpreting distance-based trees, which tend to spread out discrete evolutionary events across multiple branches.

Resolving Monophyly and Homoplasy

Traits can either be **monophyletic** or **non-monophyletic**. Monophyletic traits are shared by all members of a clade, such as leucine (or valine) in Fig. 6(c). Non-mono-phyletic traits exclude one or more members of the clade, such as leucine (but not valine) in Fig. 6(b). Correct tree rooting can distinguish these scenarios (Fig. 6).

Fig. 6 Ancestral sequence assignment and rooting. (a) Five sequences have either a leucine (L) or valine (V) at a site of interest. Parsimony can be used to assign the ancestral states of internal nodes even in the absence of a root but the state of the last common ancestor and direction of change is unclear. (b) Where both post-root nodes share the same state, parsimony can be used to infer the ancestral state: in this case, leucine. (c) Where post-root nodes differ in their state, the ancestral state is unclear.

Fig. 7 Resolving homoplasy. (a) This unrooted tree shows homoplasy: the white state appears twice without shared ancestry. Rooting the tree resolves the nature of this homoplasy. (b) If the root is at R_1 the ancestral state is black and the homoplasy has arisen through (parallel) convergent evolution. (c) If the root is at R_2 , the ancestral state is white and the homoplasy is the product of secondary loss, or reversion to the ancestral state.

In **Fig. 6(b)**, the leucine is **paraphyletic**, and arises from common ancestry but does not include all members of the clade. An alternative form of non-monophyly is **polyphyly**, in which the same trait appears in unrelated clades (**Fig. 7**). This is known as **homoplasy**, which is the situation where OTUs share a characteristic (either a phenotypic trait, or a specific nucleotide/residue in the same position) that is not the product of common ancestry (**homology**).

Another common reason to root a phylogenetic tree is to resolve apparent homoplasy. Correctly rooting the phylogeny can resolve whether a dispersed trait is truly homoplastic (rather than paraphyletic as in **Fig. 6(b)**). Furthermore, it can provide insight into the evolutionary history behind the homoplasy. This could be convergent (or parallel) evolution, in which the same trait independently evolves on two lineages (**Fig. 7(b)**), or secondary loss, in which a lineage reverts to the ancestral state (**Fig. 7(c)**).

Concluding Remarks

As with all analysis, there is no one-size-fits-all rule for when to root a tree and/or how carefully it needs to be done. The key thing is to make sure that the rooting is adequate for the biological question being asked – and to be wary of roots originally placed to answer a different biological question that may have different concerns and constraints.

Biographical Sketch

Rich Edwards is a Senior Lecturer in Bioinformatics in the School of Biotechnology and Biomolecular Sciences (BABS) at the University of New South Wales. Rich trained a geneticist at the University of Nottingham (UK), studying the population genetics of transposable elements in bacteria for his PhD. He moved to Dublin (Ireland) to become a full time bioinformatician in 2001, developing sequence analysis methods for the rational design of biologically active short peptides based on ancestral sequence prediction. This developed into an interest in Short Linear Motifs (SLiMs), which are short regions of proteins that mediate interactions with other proteins. Rich has developed several tools for the prediction and analysis of SLiMs, distributed in the SLiMSuite package. Rich established his lab in 2007 at the University of Southampton (UK) before moving to UNSW in 2013. Research interests in the lab stem from a fascination with molecular basis of evolutionary change and how we can harness the genetic sequence patterns left behind to make useful predictions about contemporary biological systems. Core research is divided between SLiM analysis/prediction and genomics projects. Rich has also collaborated on numerous projects involving DNA and/or protein sequence analysis.

Motivation

Applications of Phylogenies

Molecular phylogenetics is a lively field of research with a number of practical applications. Reconstructing large phylogenies, such as the bird ([Prum et al., 2015](#)) or mammal phylogeny ([Bininda-Emonds et al., 2007](#)), is of intrinsic interest to evolutionary biologists, but those phylogenies are also *the basic structures necessary to think clearly about differences between species, and to analyse those differences statistically* ([Felsenstein, 2004](#)). They arise frequently in comparative genomics, conservation issues ([Bordewich et al., 2008](#)), functional prediction of genes ([Eisen, 1998](#)) and more generally are at the heart of phylogenetic comparative methods ([Revell et al., 2008](#); [Pennell and Harmon, 2013](#)). Most, if not all, applications of phylogenetics have in common that they rely on accurate phylogenetic trees and it is crucial to validate the tree as different trees can lead to vastly different conclusions concerning the origin and evolution of a trait ([Geneva et al., 2015](#)).

With the advent of molecular data and increased formalism of the field ([Gascuel, 2005](#)), modern phylogenetic reconstruction is now essentially a statistical inference problem. Many popular reconstruction softwares such as PhyML ([Guindon and Gascuel, 2003](#)), RAxML ([Stamatakis, 2006](#)), FastTree ([Price et al., 2010](#)) or MrBayes ([Ronquist and Huelsenbeck, 2003](#)) produce a statistical estimate of the tree and we therefore frame validation in a statistical framework. We first discuss the different sources of inaccuracies in the reconstructed tree (Section Sources of Error) and distinguish between natural variability ($\approx$ variance) and modeling errors ($\approx$ bias). We then briefly describe and discuss popular support values (Section Robustness) aimed at validating a tree. In addition to support values, the variability observed in a forest of trees, can be summarized in order to produce robust tree estimates (Section Consensus Methods). Finally, we end this article by reviewing promising developments in the field of continuous distance and highlight their use for validation (Section Detection of Conicting Phylogenetic Signals).

Validating the Tree

A tree is a complex object that encodes the evolutionary relationship of a set of species. Many inference methods return a single focal tree and validation is most often concerned with it. There are two families of validation methods based on (i) the scale at which validation is performed and (ii) whether the tree is considered by itself or with respect to other trees.

- The first family is *local* and grounded on the observation that a tree is uniquely determined by its branches ([Buneman, 1971](#)). A tree can thus be validated by computing a *support value* for each of its branch. Support values tell us which parts of the tree are *reliable*, in a yet to be defined way.
- The second family is *global* and considers the focal tree as a single object rather than a collection of branches. It compares it to a set of alternative trees using statistical tests ([Shimodaira and Hasegawa, 1999](#)). The tests tell us whether the tree is strictly better (i.e. a better fit to the molecular data) than the alternatives.

The two approaches have a different focus but are complimentary. In particular, global tests can be used to compute local support values.

Robust Estimate

Most softwares return the best tree for a given criteria (e.g. likelihood for PhyML and RAxML). Support values tell us whether that tree is reliable and tests tell us whether it's much better than second best or other alternatives.

However, in the presence of outlier data, the superiority of the best tree may lie exclusively in a few data points: slight changes in the molecular data may dramatically change the best tree, with deep clades moving from one position in the tree to another ([Bar-Hen et al., 2008](#)). Since molecular data are inherently noisy, it is interesting to produce *robust* trees that nearly, but not completely, optimize the criteria while being resilient to small changes in the molecular data.

A straightforward way to build a robust estimate is to start from a forest of *good* trees and summarize them in some way to build a *consensus* tree. The forest can consist of trees that are only slightly worse than the best tree (e.g. bayesian consensus) or that are inferred from slightly perturbed data (e.g. bootstrap consensus).

However, more recently, the statistical perspective that observed variability between collections of trees is interesting of itself has gained traction. This has spawned a number of modern methods that utilize the elegant mathematics of tree space to permit new data analysis methods and associated new insights in a number of different contexts.

Sources of Error

Genome-scale analyses indicate that different genes yield conflicting phylogenies. Broadly speaking, these conflicts arise from two main sources: (i) the inability of traditional reconstruction methods to deal with the complexity of molecular evolution (methodological sources) and/or (ii) genuine biological events such as lateral gene transfer (LGT), incomplete lineage sorting and others that lead to different evolutionary histories along the genome (biological sources).

Methodological factors affecting phylogenetic reconstruction include the choice of optimality criterion, limited data availability, taxon sampling and specific assumptions in the modeling of sequence evolution. Biological processes such as the natural selection, small population size, etc may also cause the gene tree to differ from the species tree. The large number of potential explanations for observed incongruences in molecular phylogenetics makes decisions of how to handle them quite difficult (Rokas *et al.*, 2003b).

Biological Sources

Biological source of errors are very diverse and among other we may cite contamination, frameshift events, incorrect annotations, erroneous chimerical sequences, wrong orthology assessment, horizontal gene transfer, gene conversion, incomplete lineage sorting or hybridization, etc. (see Philippe *et al.*, 2017 for a survey).

With the improvement of sequencing technologies, the amount and quality of molecular data used in phylogenetics has drastically increased to the point where sequence quality is superseded by other concerns. For example, inclusion of non-orthologous sequences in a study can have drastic consequences on the final results (Laurin-Lemay *et al.*, 2012; Philippe *et al.*, 2011b). It can, for example, arise through undetected contamination of the genetic material during the sampling or sequencing steps (cross-contamination). It can also arise when paralogs are misidentified as orthologs, a common occurrence given the high frequency of gene/genome duplication, gene conversion and gene loss.

Finally, correct alignments are of crucial importance in phylogenetics as repeatedly pointed out (Morrison and Ellis, 1997; Ogden and Rosenberg, 2006; Talavera and Castresana, 2007; Wong *et al.*, 2008). Yet, due to the lack of tractable models of sequence evolution in the presence of insertion and deletion events (indels), the criteria optimized by alignment software are mostly *ad hoc* and based on the simplistic assumptions that homologous characters should be similar and that indels are rare events.

Modeling Errors

Every model is only a rough sketch of the complex reality of molecular evolution. First and foremost, the assumption of independent and identical evolutionary forces across sites is certainly not true in reality (Adrian, 1986; Yu and Jeffrey, 2006). What happens at one site depends both on its genomic context and on its interaction with other sites in the secondary and ternary structures of the molecule. Some relaxation allow sites to evolve at different sites (Goldman and Yang, 1994). Formally, each site has its own rate, modeled as a random effect drawn from a gamma distribution. Felsenstein and Churchill (1996) extended this approach to allow the rate at one site to depend on neighbouring sites rates using a hidden Markov model. This model captures dependence on the local genomic context (primary structure) and others have also been developed for dependence induced by proximity of sites in the secondary and ternary structure (Robinson *et al.*, 2003) but they are too complex for routine analyses.

For protein evolution, the rate matrices used to model evolution (e.g. JTT, PAM, LG, etc.) are derived by averaging over patterns observed in thousands of sites. However it is clear (Halpern and Bruno, 1998; Parisi and Echave, 2001; Susko *et al.*, 2002) that observed amino acid frequencies strongly deviate from the one expected under the JTT matrix. Lartillot and Philippe (2004) implemented a Bayesian mixture model which allows the inference of site specific rate matrices. These studies show that relaxing the assumption that all sites evolve according to the same rate matrices is crucial for accurate phylogenetic inference. However, such parameter-rich pose problems of their own, which can be difficult to diagnose (see Rannala (2002), for a discussion of over-parameterization in the context of Bayesian phylogenetic inference).

Additionally, many models assume stationarity, homogeneity and reversibility of sequence evolution. This is at odds with observations in archaea, where evolution exhibit a trend towards some nucleotides over very long time scales (Boussau and Gouy, 2006). In bacteria, codon usage bias (ref codon usage bias) can lead to non reversible evolution and different underlying stationarity state frequencies in different parts of the tree. If distantly related lineages begin to display similar state frequencies, these lineages can be artefactually grouped together when using evolution model that do not explicitly allow it (see for example Foster, 2004; Jermini *et al.*, 2004). Finally, phylogenetic trees are probably not the adequate tool to analyse and represent non-vertical transmission and reticulated evolution (Huson and Bryant, 2005).

Robustness

As discussed in Section Motivation, support values are a popular way to validate a focal tree. We present here the most popular ones before describing other methods to validate a tree or fortify it.

Support Values

Bootstrap

Bootstrap values (Felsenstein, 1985) are probably the most popular and easiest to understand support values. Bootstrap involves resampling with replacement from one's molecular data with to create fictional datasets, called *bootstrap replicates*, of the same size. Specifically, the molecular data is typically organized as a multiple sequence alignment (MSA) of s species $\times n$ characters. Since most models assume independent characters, we generate a replicate by sampling n characters, with replacement, from the original MSA and do this B times. Note that in each replicate, some characters are sampled more than once and some left out entirely. The B replicates are used to estimate a forest of B bootstrap trees (one per replicate). Finally the bootstrap value (BP) of a branch of the original tree is its frequency of occurrence in the forest. The process is illustrated in Fig. 1.

Intuitively, the variation obtained by resampling n sites from the original data should be the same as the variation obtained by sampling n new characters. Bootstrap values capture, among other, the *sampling* variability induced by short MSA. When n increases, so does BP in general and it is quite common to achieve very high values for all branches when working on genome-scale alignments (Rokas *et al.*, 2003a).

BP provides a guide for the amount of support a branch has: branches with high BP occur more often and are more reliable than those with low BP . Although it might be tempting to interpret BP as the probability that a branch is present in the (unknown) true tree, this is not the case in general. Zharkikh and Li (1992) showed in a simple case that BP is biased and underestimates that probability. Using simulation studies, Hillis and Bull (1993) showed that BP values as small as 70% could react highly supported branches. Many studies (Felsenstein and Kishino, 1993; Efron *et al.*, 1996; Susko, 2008, 2010) examined the theoretical properties of bootstrap values and concluded that they are indeed biased. This bias is partly induced by the peculiar geometry of tree space (see Billera *et al.*, 2001; Susko (2010); Section Detection of Conicting Phylogenetic Signals).

The final limitation of bootstrap values, shared with other support values based on resampling techniques, is their high computational cost: the budget required to compute B bootstrap trees is B -times higher than the budget for the original tree. Clever implementations can substantially reduce that cost (Stamatakis, 2014) but it remains prohibitive for very large trees.

Posterior probabilities

Posterior Probabilities (PP) are mostly used in a Bayesian framework and similar in spirit bootstrap values. The main difference lies in the forest of trees used to compute support values. Bayesian procedures estimate the posterior distribution of trees. In practice, the distribution is too complex to fully explore and software produce a Monte Carlo Markov Chain (MCMC) sample from the posterior distribution (Yang and Rannala, 1997). The PP of a branch is computed, just like BP , as the probability of occurrence

Fig. 1 Principle of the bootstrap for phylogenies. Each character is identified by its color and style. Characters are sampled with replacement to produce bootstrap replicates, which are then used to infer phylogenies. The split $A|BC$ appears in 2 out of 3 bootstrap trees and therefore has a bootstrap value of $BP=2/3$ or 66%.

of that branch in the MCMC sample. MCMC trees constitute a set of highly likely trees for the original dataset. *PP* are easier to interpret than *BP* as they approximate directly the probability that a branch is present in the true tree, given the original data. Furthermore, since MCMC trees are a natural byproduct of the bayesian estimation procedure, there is almost no overhead in computing *PP*.

Unfortunately, *PP* are not immune to bias. Empirical studies found that *PP* are generally higher than *BP* (Anisimova *et al.*, 2011) and sometimes even overconfident, with the “star-tree paradox” (Yang, 2007) being the perfect example of overconfidence. Yang (2007) showed that when the actual tree is a 3-species star tree, so that all 3 potential inner branches are wrong, the bayesian method picks at random whose *PP* goes to 100% when sequence length goes to infinity, whereas one could expect the *PP* to fluctuate around 33%.

Intuitively, *PP* are higher than *BP* because they cover fewer sources of variability. Unlike bootstrap trees, MCMC trees all originate from the same dataset. *PP* are quite good at capturing the lack of phylogenetic signal in the original MSA but not the impact of a few influential characters. For example, outlier characters with a strong effect on the tree or a tiny majority of character that favor one inner branch over another will affect all MCMC trees consistently. By contrast, they will be included in some bootstrap replicates but left out from others leading to more variation among bootstrap trees than among MCMC trees. Finally, in genome-scale context where inaccuracies are more likely to arise from modeling errors than from sampling variability, *PP* are uniformly high and as uninformative as *BP* (Philippe *et al.*, 2011a; Kumar *et al.*, 2012).

Likelihood-based support values

Both *BP* and *PP* quantify the agreement between a focal tree and forest of trees. Likelihood-based supports are fast alternatives that bypass the need for a forest and deal exclusively with the focal tree (Anisimova and Gascuel, 2006).

For any inner branch in the focal tree, there are 3 NNI configurations around that branch: the focal one T_1 and two alternatives T_2 , T_3 (see Fig. 2). If we note $\ell_i = \log \Pr(D|T_i)$ the likelihood of the data under tree i and assume that T_1 is the maximum-likelihood tree, we have $\ell_1 \geq \max(\ell_2, \ell_3)$. Likelihood-based supports values essentially test whether $\delta = \ell_1 - \max(\ell_2, \ell_3)$ is significantly larger than 0.

The most popular support values are:

- the approximate Likelihood Ratio Tests (aLRT) values which evaluates the statistics δ and compares it to $0.5\chi_0^2 + 0.5\chi_1^2$ to compute a p-value. The p-value is then converted into a support value between 1/8 and 1. A branch with high δ will have high support.
- the SH-corrected aLRT (SH-aLRT) values are based on the same idea but use the non-parametric (Shimodaira and Hasegawa, 1999) procedure to compute the p-value of δ .
- Finally approximate bayes (aBayes) is an approximation of the posterior probability of tree T_i computed as:

$$\Pr(T_i|D) = \frac{\Pr(T_i)\Pr(D|T_i)}{\sum_{j=1}^3 \Pr(T_j)\Pr(D|T_j)}$$

with a flat prior $\Pr(T_1) = \Pr(T_2) = \Pr(T_3)$.

All likelihood-based supports (aBayes, aLRT, SH-aLRT) amount to testing if T_1 is significantly better than T_2 and T_3 . By focusing on one branch at the time rather than questioning the whole tree, likelihood-based supports are less conservative than *BP* and *PP*. They can also recycle likelihood computed while estimating the focal tree and are therefore much faster to compute than standard *BP*. Finally, they proved to be accurate in simulations studies (Anisimova *et al.*, 2011). They are the default support values in PhyML (Guindon and Gascuel, 2003).

Outliers in the Data

The aforementioned support values aggregate all variations in the data set and are unable to pinpoint variation due to outliers. The nature of resampling techniques is to use the empirical distribution as a surrogate for the true distribution. However, the empirical distribution may be polluted by outliers, defined here as “entry in the data set that are anomalous with respect to the behavior seen in the majority of the other entries in the data set” (Barnett and Lewis, 1994). This is a common occurrence in multi-locus studies where some characters can evolve according to one a tree, and others according to another tree (Degnan and Rosenberg, 2009). In

Fig. 2 The maximum likelihood tree (T_1 , left) and its two NNI-alternatives (T_2 , middle and T_3 right) corresponding to different resolutions of the inner branch. Subtrees are sketched as triangles.

that case, a single phylogeny is not a good fit to all the characters and (Swofford *et al.*, 1996) argued that it should be interesting to pinpoint where the phylogeny is not a good fit of the molecular data. Restricting the analyses to congruent characters usually leads to higher support values (Bar-Hen *et al.*, 2008).

Several approaches have been developed to identify outlier characters. Many studies (Rodríguez-Ezpeleta *et al.*, 2007; Burleigh and Mathews, 2004) advocate removing fast-evolving characters which are a well-known cause of misleading phylogenetic signal and long branch attraction (LBA) where distantly related taxa are grouped together in the tree due to parallel or convergent evolution (Felsenstein, 1978). Lopez *et al.* (1999) also suggest to investigate and remove characters with high rate variations (i.e. fast-evolving in some parts of the tree, slow-evolving in others). However both methods assume that good topologies are available to accurately estimate rates, leading to a circularity problem.

Bar-Hen *et al.* (2008) adapted instead inuence functions (Hampel, 1974) to phylogenetics in order to assess the impact of a single site on the likelihood. The main idea consists in removing one character at a time, to create *jackknife* replicates, and to infer a tree on each replicate. Jackknife trees are used to find influential characters whose removal most affect the tree likelihood. Bar-Hen *et al.* (2008) report that influential sites have a strong impact on the topology and correspond mostly to fast evolving sites. All approaches found that removing outliers leads to more stable phylogenies but none is available as a routine in popular softwares.

Taxon Sampling

In phylogenomics studies, it is common to have conflicting trees with support values higher than 95% for all inner branches (Rydin and Källersjö, 2002). This correspond to setups where the estimated tree has a very small estimation variance and differences between inferred trees result mostly from bias and modeling errors. In particular, Swofford *et al.* (1996) argues that adequate taxon sampling is one of the primary factors for accurate phylogenetic estimates, on par with enough sequence data. For example, dense taxon sampling can reduce the impact of LBA by splitting long branches. Similarly, Holland *et al.* (2003) and Shavit *et al.* (2007) showed that the inclusion of an outgroup to the analysis may disrupt the ingroup phylogeny. When there are only a few taxa, but many characters, phylogenetic analysis can produce high support values (BP, PP, etc.) for incorrect or misleading phylogenies (Rokas *et al.*, 2003a; Rokas and Carroll, 2005; Heath *et al.*, 2008).

Analysis of sensitivity to taxon inclusion should be a part of careful and thorough phylogenetic analysis (Heath *et al.*, 2008). Mariadassou *et al.* (2012) defined a the Taxon Inuence Index (TII) to assess the inuence of each taxon on the phylogeny. Using any inference method, we define T^* to be the tree inferred from the complete MSA. Let T_k be a smaller tree, inferred from the alignment deprived of taxon k and T_k^* the tree obtained by pruning taxon k from T^* . The TII is the distance between trees T_k and T_k^* , such that

$$TII(k) = d(T_k, T_k^*)$$

They found that most taxa have small TII(k) and little inuence on the topology whereas a few are highly influential *rogue taxa* and alter the phylogeny in clades even loosely related to their placement in the tree. Aberer *et al.* (2013) use a different approach to find rogue taxa, they start from a forest of trees (e.g. bootstrap trees) and search for a small set of taxa whose pruning increases the agreement between trees in the forest. The method is implemented in the webservice RogueNarok. The rationale in both cases is that reliable trees over smaller taxa sets are preferable over uncertain trees of larger taxa sets. Both methods find that pruning rogue taxa improves accuracy and results in more stable phylogenies with higher support values.

Consensus Methods

Bootstrap, jackknife and bayesian estimation naturally produce a forest of trees with the same species set. But different trees can also be estimated by using different methods or different sources of data. One way to summarize the forest is to *project* it on a focal tree to compute support values (see Section Robustness). Testing Alternatively, one can bypass the focal tree altogether and combine all trees in the forest to get a single tree. That is the purpose of consensus trees methods.

Consensus Trees

Consensus trees are trees that summarize a forest of trees with the same species set. We present here only the *strict* consensus, the *majority rule* consensus and the *extended majority rule* consensus but there are many other consensus (see Bryant (2003) for an extensive survey). The different notions are best understood on an example. Consider the forest featured in Fig. 3 with 40 copies of trees T_1 , 48 of tree T_2 and 12 of tree T_3 . Each tree is completely defined by the bipartitions it induces (or clades for rooted trees). For example, T_1 induces the partitions ABCDEF, ABCDEF and ABEFCD (or clades AB, CD, EF and CDEF if considered as rooted), in addition to all trivial partitions ABCDEF, BACDEF, etc. not shown in the figure. Our three consensus methods scan the forest to build a list of all partitions occurring in the forest with their frequency of occurrence (middle column of Fig. 3). They then select a subset of partitions according to some rules and build a consensus tree from that subset only.

Strict consensus

The *strict consensus* tree (Rohlf, 1982) only uses partitions that appear in all trees, i.e. with a 100% occurrence frequency. The strict consensus is fully compatible with all trees in the forest. However, it is less resolved than any tree and usually too strict. In our

Fig. 3 Left: a forest of 100 trees, corresponding to 3 topologies. Each colored cross correspond to a non trivial bipartition. Middle: Set of all bipartitions, with their occurrence frequencies, found in the forest. Right: Different consensus made up by increasing large sets of partitions.

example, T_1 and T_2 and T_3 only differ in the position of D : if we removed D from all trees, they would be identical. We could therefore expect a branch separating EF from ABC . However, the set $CDEF$ is completely unresolved in the strict consensus.

Majority-rule consensus

The *majority-rule* consensus tree (Margush and McMorris, 1981) relaxes the condition that a bipartition must appear in all trees to be included in the consensus. Instead, it must only appear in *most* trees, i.e. have a occurrence frequency higher than 50%. Although not obvious, all such partitions are pairwise-compatible and can be used to build a proper tree (Buneman, 1971). The majority-rule tree is more resolved than the strict consensus one but is not compatible with all trees in the forest. In our example, the partition $ABCD|EF$ seen in the majority-rule consensus is in conflict with the partition $ABCF|DE$ present in T_2 .

Extended majority-rule consensus

The *extended majority-rule* consensus (Felsenstein, 2005), also called greedy consensus, relaxes the occurrence frequency condition even further. The consensus is build by sequentially adding partition one at a time, in decreasing order of occurrence and only if compatible with previously included partitions, until the tree is fully resolved or no more partitions can be added. Since all partitions with frequency higher than 50% are compatible, they are part of the selection and the greedy consensus is thus a refinement of the majority-rule consensus. In our example, after including partitions $ABCD|EF$ and $AB|CDEF$, we can add either $ABCF|DE$ or $ABEF|CD$. The latter is in conflict with $ABCD|EF$ and thus not included whereas the former is compatible with both partitions and thus included. After addition of $ABCF|DE$, the greedy consensus is fully resolved. Note that the greedy consensus is different from all trees in the forest.

Branch lengths in consensus trees

The strict, majority-rule and extended majority-rule consensus trees only use *topologies* and produce consensus topologies. One way to add branch lengths to that consensus is to take, for each branch, its average length over trees where it is present. This is the approach used in MrBayes (Ronquist and Huelsenbeck, 2003) when building a consensus tree from the sample of posterior trees.

Distance-Based Consensus

The previous consensus methods are easy to understand and implement. Some also have a theoretical grounding that leads to generalizations. Barthélemy and McMorris (1986) showed that the majority-rule consensus is the *center* of the forest in the sense that it minimizes the sum of Robinson-Foulds distances (Robinson and Foulds, 1979) to all trees in the forest. It is thus the forest *median tree*. One could minimize total squared distance to all trees in the forest to find the *mean tree*.

The Robinson-Foulds is but one of many distances between trees (see St. John (2017) for an excellent review) and one can define other consensus similarly as the forest mean or median tree for some distance between tree. Although seducing, this approach suffered in the past from two shortcomings that severely limit its use. First, it was not obvious that the mean, or median, tree is well-defined or unique for some distances (Billera et al., 2001). Second, even when the mean was well-defined, there was no routine to compute it in practice. Recent progress in the field (Miller et al., 2015a) have made it easier to compute sophisticated distances and use them to validate trees.

Detection of Conflicting Phylogenetic Signals

The very idea of a consensus tree relies on the existence of a *center* around which trees are distributed. However, trees that are far away from the consensus can be the sign of either high variability or conflicting signals. While high variability implies weak phylogenetic signal, conflicting signals implies incongruence in the underlying data. Most distances, such as RF, are discrete and lead to very coarse information about the tree distribution. By contrast, continuous distances are a natural way to characterize variance and distinguish high variability from conflicting signals. Moreover continuous distance lend themselves nicely to other standard aspects of inferential statistics such as confidence sets and hypothesis testing.

The geometric model of Billera *et al.* (2001) allows one to compare phylogenetic trees with the same taxa set (of size m) in a quantitative way. This space has a natural metric, giving a way of measuring *continuous* distances between phylogenies and providing some procedures for averaging or combining several trees with the same leaves. This geometry also shows which trees appear within a fixed distance of a given tree and enables one to build confidence convex hulls from a set of trees. It also provides a justification for calling outliers in a collection of otherwise congruent trees and limit the consensus to those congruent tree.

Tree Space Definition

The distance $d(T, T')$ between two trees T and T' accounts for differences with respect to both their tree topologies (branching structure) and branch lengths. The space is constructed by representing each of the $(2m - 3)!!$ possible tree topologies by a single non-negative Euclidean orthant of dimension $m - 3$ (the largest possible number of internal branches). The orthants are then “glued together” along appropriate axes. Specifically, nearest neighbor interchange (NNI) topologies lie in adjacent non-negative orthants along the boundary corresponding to the collapse of the relevant NNI edge.

For two trees with different topologies, the BHV distance is the length of the shortest path that link them in the treespace. The length of any path can be computed by calculating the Euclidean distance of the path restricted to each orthant that it passes through, and summing these lengths. The shortest path is called a geodesic, and will pass from one orthant to the next orthant through lower-dimensional boundaries corresponding to less resolved trees. Since the space is nonpositively curved, the geodesics are unique (Fig. 4).

Fig. 4 Orthants in the BHV space of trees with 4 leaves and examples of two geodesics. As illustrated, the geodesics are not identical and therefore depend on both the topology and the actual branch lengths. Reproduced from Brown, D.G., Owen, M., 2017. Mean and variance of phylogenetic trees. arXiv preprint [arXiv:1708.00294](https://arxiv.org/abs/1708.00294).

In Euclidean space, the Fréchet mean is the point minimizing the sum of the squared distances to the sample points, and is equivalent to the coordinate-wise average of the sample points. Similarly, the Fréchet mean tree is the tree minimizing the sum of squared BHV distances to a set of trees and that sum is the variance which quantifies how spread out the forest is (Miller *et al.* (2015b) and Brown and Owen (2017)). Billera *et al.* (2001) showed that mean is unique and is not necessarily a refinement of the majority-rule consensus.

Use of BHV Distance

BHV distances can be used in much the same way as euclidian distance and the standard tools of multivariate statistics can be used to analyse the forest. For example, Barden *et al.* (2014) proved a Central Limit Theorem in the BHV space that can be used to either detect weakly and strongly supported edges in the mean tree or to test hypotheses on some portion of the tree. One of their main tool is the so-called log-map which projects the BHV metric space to the usual euclidian space and allows one to visualize the forest as a scatter plot to gain some understanding of the estimate uncertainty.

In the same spirit, Willis (2016) use the distance matrix to estimate the principal directions of variability *via* principal components analysis (PCA). The axes of the $\mathbb{R}^m$ ellipsoid indicate the relative directions of precision, and the ellipsoid can be shrunk to be wholly contained in the same orthant as a focal tree $\hat{T}$. This gives an unambiguous indication of the relative confidence in the edges of $\hat{T}$. Note that the procedure is also explicit about the trees contained in the confidence set for a given confidence level α . de Vienne *et al.* (2012) use a similar approach based on a different mapping of the trees to a euclidian space and use multiple co-inertia analysis (MCOA) instead of PCA to detect the principal directions of variability.

Finally Weyenberg *et al.* (2014) propose a non-parametric estimator of the distribution that generated the forest $T_1, \dots, T_n$. This estimator can be viewed as a refined version of histogram-based estimation of a density. The kernel function, is a non-negative function defined on pairs of trees, which measures how similar two trees are. Kernel density estimation use the fact that points close to sample points tend to have higher likelihood than distant outlier points. The ultimate goal is to detect outlier trees, T_j , which are not actually drawn from the true distribution.

Conclusions

Nowadays efficient algorithms permit to compute means of continuous distances in a reasonable time. Moreover a huge amount of work has been done to derive mathematical properties of these distances. Therefore it is possible to go from a theoretical work to applications. For example, Kendall and Colijn (2016) use tree mapping to show that 3 genes of Ebolavirus have markedly different phylogenies. This result is quite typical in genomic-scales analysis where different loci have different evolution history. This is a natural consequence of the gene trees/species tree problem whereby the evolutionary history of a gene can be different from the species tree (Degnan and Rosenberg, 2009). This has spanned the entire research field of reconciliation devoted to the reconstruction of species tree from sets of gene tree.

Distances between trees can help cluster trees and/or loci into congruent groups with the intent of performing one inference per group to infer more robust phylogenetic estimates. In an era of cheap and abundant sequences, tree validation is as much a matter of computing support values as a matter of validating and making sure there are not too many conflicting signals in the molecular data (taxa set, gene set) used for tree reconstruction.

Applications of the Coalescent for the Evolutionary Analysis of Genetic Data

Miguel Arenas, University of Vigo, Vigo, Spain

© 2019 Elsevier Inc. All rights reserved.

Introduction

The coalescent (Kingman, 1982) is a stochastic model to simulate the evolutionary history of a sample of a large population. Instead of simulating the entire population and then sampling, the coalescent simulates the history of the sample to its most recent common ancestor (MRCA). The population size is considered in the coalescent but only to determine the probability of coalescent events, not to simulate the population history (Section “The Coalescent Theory and its Extensions”). As a consequence, coalescent simulations are generally rapid, which is convenient for a variety of applications.

First coalescent approaches were rapidly extended to mimic diverse fundamental evolutionary processes such as recombination (Hudson and Kaplan, 1988; Kaplan *et al.*, 1991; Hudson, 1990), population structure with migration (Hudson, 1998; Kaplan *et al.*, 1991; Hudson, 1990) and selection (Hudson and Kaplan, 1988, 1995; Kaplan *et al.*, 1988, 1991; Hudson, 1990) (Section “The Coalescent Theory and its Extensions”), with goals but also with limitations (Section “Goals and Limitations of the Coalescent”). All these extensions were implemented into a variety of evolutionary frameworks (Section “Coalescent Simulators”). The coalescent can be applied to address diverse evolutionary questions (Section “Applications of the Coalescent”). For example, it can be used for hypothesis testing, validation of analytical methods, selection of evolutionary models and estimation of evolutionary parameters.

This article revises the current state of the coalescent with a special focus on its applications. First, it provides a brief introduction on the fundamental insights of the standard coalescent and its extensions (some complementary reviews are provided). Next it describes goals and limitations of the coalescent, currently available coalescent simulators and applications in population genetics and evolution. Finally, the article provides suggestions to design a coalescent-based experiment, including some practical examples.

The Coalescent Theory and Its Extensions

The standard coalescent only requires sample size (k) and effective population size (N) to simulate the evolutionary history of a sample. This simulation is based on a backwards in time process, where the sample is evolved from the present to the past (Fig. 1). The probability that two individuals descend from a common ancestor of the population is $1/2N$. Thus, the probability of a coalescent event between two lineages of a sample of k individuals can be obtained by calculating, $1/2N \times k(k-1)/2 = k(k-1)/4N$, because there are $k(k-1)/2$ pairs of individuals in a sample of k individuals (note that if k is 2 the result is again $1/2N$). Fig. 1 presents the probabilities of coalescent events in an illustrative example. Next, considering that the time for a coalescent event follows an exponential distribution (for $k=2$, $P(t+1) = (1 - (1/2N))^t \times (1/2N) \approx (1/2N)e^{-t/2N}$), the expectation of this time is

Fig. 1 Illustrative example of the standard coalescent. Simulation of a coalescent tree from a sample of six individuals (circles in clear grey) and population size N . Coalescent events generate internal nodes (circles in dark grey) that are simulated going backwards in time until reaching only one active lineage, the MRCA (circle in black). For each period of time before a coalescent event the following information is shown: number of active lineages k , probability of a coalescence P and expected time for a coalescence T .

$E(T_k) = 4N/k(k-1)$. These expressions require $4N/k(k-1) \gg 1$ that only works when the sample size is much smaller than the population size, which is one of the most important assumptions of the coalescent. The time to the MRCA (TMRCA) can be obtained by summing coalescence times from k to 2 individuals, $E(T_{MRCA}) = E(T_k) + E(T_{k-1}) + E(T_{k-2}) + \dots + E(T_{k=2}) = 4N(1 - 1/k)$. Interestingly, note that the last coalescent event (when $k=2$) requires $2N$ generations, which is almost half of the time required to reach the MRCA. Further details about the mathematical expressions of the coalescent can be found in the following reviews (Nordborg, 2007; Neuhauser and Tavaré, 2001; Hein *et al.*, 2005). It follows with an overview on the most relevant extensions of the standard coalescent.

The Coalescent With Variable Population Size

Fluctuations in population size through time are common and, consequently, one of the first extensions of the coalescent was oriented to consider this aspect. As noted above, the probability or expected time for a coalescent event depends on the population size. The larger is the population size, the smaller is the probability of a coalescent event or the longer is the expected time for a coalescent event, which leads to longer branch lengths (Fig. 2(B)). Thus, if the population size increased over time (it decreased if we go back in time) longer branches are expected to appear near present (coalescences mainly appear in the past) leading to a star-like tree (Fig. 2(A)). By contrast, if population size decreases through time, longer branches are expected to appear in the past, leading to trees with a comb-like shape (Fig. 2(C)).

The variation of the population size through time can be systematic or irregular. A systematic variation can be modeled with only a few parameters (i.e., the commonly used population growth rate g where $N(t) = N_{(0)} \times e^{-gt}$) that can be easily incorporated to the coalescent. However, the population size could also vary in a different manner at different periods of time (i.e., as it occurs many times in virus populations (Lemey *et al.*, 2006)). Since these demographic periods may not be coincident with times between coalescent events, the implementation of this scenario is slightly more complex (details in Hein *et al.* (2005)). An interesting scenario is a population bottleneck (an important decline in population size during a period of time). During a bottleneck the population size can be very small and, consequently, the rate of coalescence will increase reducing the TMRCA (Hein *et al.*, 2005).

The Coalescent With Population Structure and Migration

Sometimes individuals may only mate with others that present particular features (i.e., proximity or phenotype). Under these situations, one can devise a model where a population structure defined as a set of subpopulations (or demes) presents mating (coalescence) only between individuals of the same deme but with possible migration of individuals between demes (Fig. 3). If the sample comes from different demes and there is not a connection between them (i.e., lack of a demes tree and/or migration between demes) the coalescent cannot be applied because a MRCA common to all demes cannot be reached: migration or demes coalescence is required to coalesce all the lineages. Migration rate can affect both topology and branch lengths. The smaller is the migration rate, the longer is the expected TMRCA (Hein *et al.*, 2005). Nevertheless, migration can be modeled as a process independent of coalescence and recombination and, consequently, it can be easily considered to determine the probability or expected time of coalescent and migration events (Hein *et al.*, 2005; Notohara, 1990). For mathematical details about probabilities and expected times of migration and coalescence events the reader is referred to Hein *et al.* (2005). The choice of a receiving deme in a migration event depends on the specified subdivision (migration) model and migration rates (Fig. 4(A)). The most used migration model in the coalescent is the island model where all demes can exchange individuals with all demes (Hudson, 1998). The stepping stone migration model (Kimura and Weiss, 1964), where demes only exchange migrants with neighboring demes, is also well-established. Another useful model is the continent-island model that considers migration between a central deme and peripheral demes (Wright, 1931). The coalescent can also be structured considering a demes tree (Nielsen and Wakeley, 2001; Fig. 4(B)). Under this scenario, demes share a common ancestor and migration is not mandatory to reach the MRCA.

The Coalescent With Recombination

Recombination is a fundamental evolutionary force for most organisms, especially virus and bacteria (Perez-Losada *et al.*, 2015). Recombination events generate an ancestral recombination graph (ARG) (Arenas, 2013b; Griffiths and Marjoram, 1997, 1996)

Fig. 2 Illustrative example of the influence of the population size on the coalescent process. The variation of the population size through time is shown with grey dashed lines. (B) Coalescent tree simulated with constant population size ($N(t) = N_{(0)}$). (A) Coalescent tree simulated with a positive population growth rate (population size increases with time, $N(t) > N_{(0)}$). (C) Coalescent tree simulated with a negative population growth rate (population size decreases with time, $N(t) < N_{(0)}$).

Fig. 3 Illustrative example of the coalescent with population structure and migration. Simulation of a coalescent tree from a sample of six individuals (circles at the present) that belong to two different demes (deme 1 in clear grey and deme 2 in dark grey). Coalescent events generate internal nodes (circles). Migration events are depicted with dashed lines. The process occurs going backwards in time until reaching the MRCA (circle in black).

Fig. 4 Migration models and the coalescent within a demes tree. (A) Migration or subdivision models: Island model (top), continent-island model (middle), stepping stone model (bottom). (B) Simulation of a coalescent tree within a demes tree with migration. Migration events are depicted with dashed lines. The process occurs going backwards in time until reaching the MRCA.

where genomic fragments can present different evolutionary histories (**Fig. 5**) and that should be carefully considered for inferring phylogenetic trees (Schierup and Hein, 2000a; Arenas and Posada, 2010b; Mallo *et al.*, 2016; Posada and Crandall, 2002). The number of simulated recombination events is based on the population recombination rate $\rho = 4Nr$, where r is the recombination rate per generation per site and l is the sequence length. Importantly, a recombination breakpoint can only occur in sites that did not reach their MRCA yet. The expected number of recombination events in a panmictic population with constant population size and a sample of k individuals is defined as, $E(\text{number of recombination events}) = \rho \sum_{i=1}^{k-1} \frac{1}{i}$.

It is also possible to simulate the coalescent with heterogeneous recombination along the sequences. There, background (homogeneous) and hotspot (heterogeneous) recombination rates can be applied to simulate hotspot location, heterogeneity and precision (Wiuf and Posada, 2003).

An special coalescent process with recombination is the coalescent simulation of intra-codon recombination (Arenas and Posada, 2010a). Substitution models of codon evolution require complete codons to operate and a codon broken due to a recombination event can be problematic because can lead to branches assigned to incomplete codons. This problem was solved by Arenas and Posada (2010a) with a coalescent algorithm where ancestral material that does not belong to the sample but that is required to complete broken codons (called as pseudo-ancestral material) can be considered in the coalescent, leading to slightly longer ARGs but allowing codon models to operate (Arenas and Posada, 2012).

Fig. 5 Illustrative example of an ancestral recombination graph with a tree for each recombinant partition. Ancestral recombination graph for a sample of 4 sequences (A, B, C, D) with 9 sites (i.e., nucleotides). A recombination event (RE, dashed line) occurs with breakpoint at position 5, leading to the recombinant partitions 1–5 and 6–9. Each recombinant partition presents a particular coalescent tree (depicted on the right).

The Coalescent With Selection

Previous coalescent approaches assume neutral evolution. However, in the real world, some lineages may present a higher fitness (i.e., better adapted to the environment) than others. Therefore, the coalescent was also extended to mimic selection through two main approaches.

The first one is the simulation of the ancestral selection graph (ASG) (Krone and Neuhauser, 1997; Neuhauser and Krone, 1997). The ASG presents the genealogy of the lineages (or alleles) into a graph based on coalescence and branching events, similar to the ARG (Fig. 5), where removing branches (i.e., alleles with low fitness) can lead to a tree. The ASG is especially useful to simulate evolutionary histories under weak selection (moderate or strong selection in the ASG may not be computationally tractable). It was later extended to model ancestry conditioned on the frequencies of the selected alleles (Slade and Neuhauser, 2003; Slade, 2000a,b) and even to population subdivision and migration (Slade and Wakeley, 2005).

The other approach is the conditional structured coalescent (Kaplan *et al.*, 1988; Hudson and Kaplan, 1988) where historical allele frequencies are used to generate classes or subpopulations based on their levels of selection. There is not selection within each subpopulation but each subpopulation may present specific values for parameters such as population size or population growth rate. The methods for the coalescent with population structure and migration (see above) can thus be applied to this approach. A migration event can be considered as a mutation or a recombination event (i.e., a beneficial mutation or recombination event could move an allele from low to high selection – or the opposite –, thus moving it from a particular subpopulation to another one). Some examples of this approach involving balancing selection, background selection and selective sweeps are detailed described in Nordborg (2007).

Goals and Limitations of the Coalescent

In addition to the coalescent, some other approaches have been developed to simulate evolutionary histories in population genetics (Arenas, 2012; Hoban *et al.*, 2012). One of the most relevant is the forward in time approach, which simulates the evolutionary history of the entire population from the past to the present (Peng *et al.*, 2012; Carvajal-Rodriguez, 2010). Simulations generated with the forward in time approach consider the ancestral information of the entire population and are useful to study diverse complex evolutionary processes such as mating systems and complex migration (i.e., sex biased dispersal or long-distance dispersal) (e.g., Alves *et al.*, 2016; Rasteiro *et al.*, 2012; Peng and Amos, 2008) or complex selection (Peng *et al.*, 2007) that cannot be studied with the coalescent yet. However, forward in time simulations usually require extensive computational costs and memory capacity to simulate the entire population. In this concern, coalescent simulations are generally much more efficient than forward in time simulations. The coalescent is convenient for studies that require a large number of simulations such as Bayesian (Beaumont and Rannala, 2004) and approximation Bayesian computation (ABC) (Arenas, 2015; Beaumont, 2010) approaches.

A problem in the coalescent can occur with the simulation of the ARG (and, similarly, the ASG) under very high population recombination rates (i.e., $\rho > 1000$). Under this situation the number of active lineages may dramatically increase going backwards

in time leading to computer problems related with out of memory. In addition, if the population growth rate is too negative, the TMRCA can be almost infinite, again leading to computational problems.

Coalescent Simulators

A number of freely available coalescent simulators have been developed (Table 1). Most of available coalescent simulators implement demographics, population structure and recombination. However, selection is implemented in only a few coalescent programs mainly due to its complexity (see above) in comparison with forward in time approaches (Peng *et al.*, 2012; Carvajal-Rodriguez, 2010). Current trends of coalescent frameworks include the adaptation of the coalescent to simulate specific genetic markers such as codons (Arenas and Posada, 2010a, 2007), proteins (Arenas *et al.*, 2013) or whole-genome sequences (e.g., Arenas and Posada, 2014b; Kelleher *et al.*, 2016). Another trend is to develop extensions of the coalescent to mimic the evolution of specific organisms such as bacteria (De Maio and Wilson, 2017; Brown *et al.*, 2016) and cancer (Zhao *et al.*, 2014; Nicolas *et al.*, 2007). In all, the development of coalescent simulators is a very active area of research in population genetics with a continuous emergence of more efficient, and with more capabilities, frameworks.

Applications of the Coalescent

The coalescent provides clear and rapid representations of real evolutionary processes and its implementation in computer frameworks is, in general, straightforward. Consequently, the coalescent has been applied to a variety of purposes, the most relevant are presented below.

Hypothesis Testing

The coalescent has been widely used for testing hypothesis such as the effects between evolutionary parameters or the influence of evolutionary parameters on phylogenetic reconstructions. It follows with some illustrative examples.

Computer simulations of the coalescent with recombination (Arenas, 2013a), followed by the simulation of codon evolution upon the simulated coalescent histories (Arenas and Posada, 2012), were applied in several studies to analyze the influence of ignored recombination on the estimation of selection (the nonsynonymous (dN) to synonymous (dS) substitution ratio, dN/dS or ω) (Arenas and Posada, 2010a, 2014a; Anisimova *et al.*, 2003; Shriner *et al.*, 2003). These studies found that ignored recombination biases the estimation of dN/dS by generating false positively selected sites. As a consequence, those studies concluded that recombination must be considered for the estimation of dN/dS . That can be performed by the following methodology: (i) detection of recombination breakpoints, (ii) inference of a phylogenetic tree for each recombination partition and, (iii) estimation of dN/dS per site (or per recombination partition) accounting for the corresponding phylogenetic tree. This methodology was already applied in several studies (e.g., Perez-Losada *et al.*, 2009; Perez-Losada *et al.*, 2011).

Another application of coalescent simulations was the analysis of the influence of recombination on ancestral sequence reconstruction (ASR). Arenas and Posada (2010b) performed coalescent simulations under different levels of recombination and simulated DNA sequence evolution over those coalescent histories to generate sequences for every tip and internal node. Next, they performed ASR from the simulated sample and a previously inferred ML or Bayesian phylogenetic tree, to infer the ancestral sequences. Finally, they compared the simulated (true) ancestral sequences with the inferred ancestral sequences to evaluate the impact of recombination on ASR. They found that recombination seriously bias ASR, especially under high levels of genetic diversity (Arenas and Posada, 2010b). In order to reduce this bias, they suggested that ASR should be performed for each recombinant partition independently (see below).

The influence of recombination on the estimation of dN/dS and on ASR is derived from the influence of recombination on phylogenetic tree reconstruction. Recombination can bias phylogenetic tree inferences because each recombinant partition can present an evolutionary history that differs from the evolutionary history of other recombinant partitions. This was investigated by Schierup and Hein (2000a) with coalescent simulations based on the Hudson's algorithm of the coalescent with recombination (Hudson, 1983). They found that if recombination is present but ignored, derived phylogenetic trees can be biased with incorrect topologies and branch lengths (Schierup and Hein, 2000a). Moreover, ignoring recombination can result in loss of molecular clock, apparent homoplasies and incorrect substitution rate heterogeneity (Schierup and Hein, 2000a,b). In addition, phylogenetic incongruence in empirical data was observed and attributed to ignored recombination (Worobey and Holmes, 1999; Feil *et al.*, 2001). Consequently, under the presence of recombination one should either infer a phylogenetic tree for each recombinant partition (recombinant partitions can be identified with a framework for the detection of recombination breakpoints (e.g., Martin *et al.*, 2015; Kosakovsky Pond *et al.*, 2006) (Arenas and Posada, 2010b) or infer a phylogenetic recombination network (Arenas, 2013b; Griffiths and Marjoram, 1997; Huson and Bryant, 2006; Huson, 1998). Additionally, a variety of analytical evolutionary frameworks (i.e., BEAST (Drummond *et al.*, 2012)) are based on the coalescent without recombination and can therefore generate biases from data that suffered recombination events. Detecting recombination partitions and analyzing them separately is once again recommended (e.g., Perez-Losada *et al.*, 2007).

Table 1 Main coalescent simulators and their capabilities

Program	Evolutionary scenarios	Additional capabilities	Genetic data	OS	Reference

^aThe ARG can be analyzed/visualized with *NetTest* (Arenas *et al.*, 2010).

Note. The simulators are presented by publication date, from the present to the past. The table shows: (i) implemented evolutionary scenarios (Ls, Dm, Pm, Re and Se, refers to longitudinal sampling, demographics, population structure and migration, recombination and selection, respectively); (ii) additional capabilities to the cited evolutionary scenarios; (iii) type of simulated genetic data (in addition to the simulated coalescent tree(s) like sequences of SNPs, microsatellites (STR), nucleotides (NT), codons (Cd) and amino acids (Aa); (iv) operative system (OS) considering the availability of binary files (Linux, Macintosh, Windows) and/or source code (SC); (v) references. This list is not exhaustive but is meant to highlight the diversity of the field.

Another example is the evaluation of the criteria for selecting substitution models of evolution. Luo *et al.* (2010) simulated coalescent evolutionary histories and used those trees to simulate DNA sequence evolution under different substitution models of evolution. Next, they estimated the best fitting substitution model of evolution for the simulated data under different statistical criteria such as Bayesian information criterion, decision theory, Akaike information criterion and hierarchical likelihood-ratio test. They found that Bayesian information and decision theory performed better for identifying the correct substitution model and, therefore, these criteria should be preferred in substitution model selection.

Validation of Analytical Methods

Any analytical framework must be properly validated. In population genetics, the “true” evolutionary process of a dataset is usually unknown. Therefore, the evaluation of analytical frameworks is frequently assessed with computer simulations where the “true” (simulated) evolutionary process is known. The coalescent has been widely used for the evaluation of analytical evolutionary frameworks. Some illustrative examples are described below.

It was remarkable in the previous subsection that genetic recombination should be considered in the evolutionary analysis of genetic data. Because of that, and other aspects about the important role of recombination in the evolution of many organisms (e.g., Arenas *et al.*, 2017; Castelhana *et al.*, 2017; Arenas *et al.*, 2016; Perez-Losada *et al.*, 2015), a variety of frameworks were developed to detect and quantify recombination and to infer phylogenetic recombination frameworks. Many of these frameworks were validated with the coalescent extended with recombination. The following are some examples: (i) Marttinen *et al.* (2012) with a method to detect homologous recombination events (validated comparing the number of simulated and predicted recombination events); (ii) Westesson and Holmes (2009) with a method to identify recombination breakpoints (validated comparing simulated and detected recombinant regions); (iii) Dialdestoro *et al.* (2016) with a method to estimate recombination rate and other population genetics parameters such as population size (validated comparing the distance between simulated and estimated recombination rates); (iv) White *et al.* (2013) and Sun *et al.* (2011) evaluating some of the existing recombination detection tests (validated comparing simulated and estimated recombination rate); (v) Lopes *et al.* (2014) with a method to coestimate recombination rate with other parameters of molecular evolution (also validated comparing simulated and estimated recombination rate).

Coalescent simulations are also frequently applied to evaluate reconstruction methods of phylogenetic trees (e.g., McCormack *et al.*, 2009; Chen *et al.*, 2011) and networks (e.g., Wen *et al.*, 2016; Javed *et al.*, 2011; Yu *et al.*, 2014; Yu and Nakhleh, 2015; Hassanzadeh *et al.*, 2012; Wang *et al.*, 2013) where the topology and branch lengths of simulated and reconstructed phylogenies are compared.

Coalescent simulations have also been applied to validate other analytical methods in population genetics such as the estimation of pairwise distance between sequences (Domazet-Loso and Haubold, 2009) or the estimation of population size and migration rate (Beerli, 2006).

Estimation of Evolutionary Parameters and Model Selection

A variety of computer programs based on the coalescent can estimate evolutionary parameters. Some of the most relevant are, (i) BEAST, estimation of variable population size, substitution rate and other evolutionary parameters, also phylogenetic tree reconstruction; (ii) GENETREE (Bahlo and Griffiths, 2000), estimation of population growth, mutation and migration rates; (iii) IMA (Hey and Nielsen, 2007), estimation of population size, migration rate and divergence time; (iv) LAMARC (Kuhner, 2006), estimation of population growth, migration and recombination rates; (v) MIGRATE (Beerli and Felsenstein, 2001), estimation of population size and migration rates.

The cited programs estimate evolutionary parameters through a likelihood function. However, under complex models of evolution a likelihood function could not be mathematically designed or could be computationally intractable. In these situations, the ABC approach provides a very useful alternative because it does not require the likelihood function. Moreover, ABC can outperform maximum-likelihood (ML) methods based on approximate models (Arenas *et al.*, 2015; Lopes *et al.*, 2014). Briefly, ABC provides model selection and parameters estimation by the following pipeline: (i) Design of prior distributions for parameters, these prior distributions should contain the real value. (ii) Extensive computer simulations after sampling from the prior distributions. (iii) Design and computation of summary statistics for simulated and real data. (iv) Selection of summary statistics from simulated data that are closer to the summary statistics from real data according to a given tolerance. (v) With the retained summary statistics from simulated data and summary statistics from real data, ABC applies a rejection (Pritchard *et al.*, 1999) or a multiple regression approach (Beaumont *et al.*, 2002) to obtain the posterior distributions for the studied models or parameters. For further details about the ABC approach the reader is referred to the following reviews (Beaumont, 2010; Arenas, 2015; Csillery *et al.*, 2010; Sunnaker *et al.*, 2013; Bertorelle *et al.*, 2010; Lopes and Beaumont, 2010). ABC usually requires a number of computer simulations that should be longer enough (from thousands to millions) for properly covering the prior distributions. Since the coalescent provides a rapid computation, most of ABC studies have applied the coalescent to simulate datasets (e.g., Arenas *et al.*, 2015; Lopes *et al.*, 2014; Alves *et al.*, 2016; Wilson *et al.*, 2009; Fan and Kubatko, 2011; Li and Jakobsson, 2012). Because of this important application of the coalescent, many coalescent simulators incorporate adaptations to facilitate the design of

ABC analyses (i.e., simulating from predefined prior distributions) (e.g., Arenas and Posada, 2014b; Excoffier and Foll, 2011; Pavlidis *et al.*, 2010).

Designing a Coalescent-Based Experiment

Studies involving coalescent simulations may require a previous design. The researcher has to choose a coalescent tool to simulate an evolutionary scenario and obtain a desired type of genetic data. A few aspects should be considered to design the study.

1. Evolutionary scenario. The currently available coalescent simulators implement a large variety of models to mimic diverse evolutionary scenarios (see Section “Coalescent Simulators” and Table 1). The following sentences provide suggestions from the experience of the author. The simulation of basic scenarios such as a constant population size can be easily performed with the *ms* program. This program is also useful for simulating basic (homogeneous) recombination. For scenarios with population structure and migration, the simulators *SimCoal2* and *fastsimcoal* provide a variety of parameters (i.e., a matrix of migration rates). Complex recombination (i.e., hotspots) can be simulated with *SNPsim*, which implements a wide variety of models of heterogeneous recombination. Scenarios of selection can be simulated with *mbs* and *msms*.
2. Desired output data. Any coalescent framework simulates a coalescent tree but may not simulate genetic data. Here there are two options. (i) Apply a coalescent framework that internally simulates genetic data (i.e., *CoalEvol* simulates nucleotide, codon and protein sequences under a variety of substitution models of evolution); (ii) Apply the chosen coalescent framework to simulate the coalescent history and then simulate sequence evolution (Yang, 2006) upon such a history with frameworks such as *INDELible* (Fletcher and Yang, 2009), *CoalEvol*, *SeqGen* (Rambaut and Grassly, 1997), *Pyvolve* (Spielman and Wilke, 2015) or *Phylosim* (Sipos *et al.*, 2011), see for a review (Arenas, 2012).

Illustrative Practical Examples

Here five practical examples to simulate a particular type of genetic data under a particular evolutionary scenario are presented.

1. *Codon sequences under recombination*. Probably the easiest procedure to perform this simulation is with the programs *NetRecodon* or *CoalEvol*. These programs implement the simulation of the ARG and the subsequent simulation of coding sequence evolution (under a variety of codon substitution models) over the ARG. Another possibility is to apply the program *ms* to obtain the ARG (a coalescent tree for each recombinant partition) and then apply *INDELible* (or a similar framework, see above) to simulate codon evolution upon the coalescent trees. The advantage from using the first procedure is that *NetRecodon* and *CoalEvol* implement the simulation of both intercodon and intracodon recombination, which is much more realistic than consider only intercodon recombination in the second procedure.
2. *Protein sequences under a population structure with migration*. Again, the program *CoalEvol* implements the simulation of population structure with migration and the simulation of protein sequences over the previously simulated tree. However, *CoalEvol* implements a limited number of migration parameters (i.e., same migration rate between all demes). As an alternative, one could apply *fastsimcoal*, which includes a variety of parameters to better mimic the population structure with migration, and then simulate protein sequences with *INDELible* (or similar framework).
3. *Protein sequences under selection*. First, coalescent trees under selection can be simulated with *mbs* or *msms* and then, protein sequences can be simulated over those trees with *INDELible* (or similar framework). For simulations under complex models of selection one could explore forward in time simulation frameworks (Peng *et al.*, 2012).
4. *Nucleotide sequences under heterogeneous recombination (hotspots)*. I would recommend simulate the coalescent trees (ARG) with *SNPsim* (although there are other advanced simulators such as *Cosi2*, *msHOT*, *GENOME* and *SimCoal2*) and next simulate nucleotide sequences with *INDELible* (or similar framework). Another methodology is to perform both the coalescent simulation and sequence simulation with *CoalEvol*, which implements the heterogeneous recombination models of *SNPsim*.
5. *Codon sequences with longitudinal sampling accounting for variation of the population size and population structure*. Longitudinal sampling, variable population size through time and population structure can be simulated with *Serial SimCoal*, *scrm* and *CoalEvol*. *CoalEvol* also allows the simulation of codon sequence evolution. In case of *Serial SimCoal* and *scrm*, codon sequence evolution can be simulated with *INDELible* (or similar framework).

Concluding Remarks

The coalescent is a stochastic statistical process established in population genetics for more than 30 years. Instead of reducing its popularity through time, the coalescent is progressively more famous, used and incorporated into new frameworks (usually published in important journals of the discipline because of their utility, as presented in this study) to both simulate and analyze genetic data in an evolutionary perspective.

A number of coalescent simulators exist implementing fundamental evolutionary processes of the real world such as demography, recombination, population structure and selection. Some coalescent simulators are also oriented to mimic the evolution of specific organisms such as bacteria or cancer. However, further work is required to accommodate more complex evolutionary models, especially complex selection, as done in the forward in time simulation approach.

Some famous analytical tools (i.e., *BEAST* and *LAMARC*) are based on the coalescent and consequently, users of those tools should have in mind the limitations of the underlined coalescent approach (i.e., the cited programs ignore selection). It is worth highlighting the incorporation of the coalescent into the ABC approach, which is a methodology of increasing application in population genetics and ecology to analyze genetic data under complex models of evolution. Instead of being forced to only consider the limited models implemented in ML or Bayesian tools, ABC allows the user to apply any model that can be simulated. In this concern, the coalescent provides fast simulations that are convenient to achieve the extensive number of simulations usually required in ABC.

The future of the coalescent is likely to be highly promising because of their important applications. However, we still need to develop more extensions of the coalescent, and subsequent implementation in simulation frameworks, to better fit with real evolutionary processes.

© 2019 Elsevier Inc. All rights reserved.

Nomenclature

$A_1, A_2,$	Allele types.	V_x	The random number of offspring of individual x in the Cannings and Bienaymé-Galton-Watson models.
$B(\cdot, \cdot)$	The beta function.	$X(t)$	In the diffusion limit, relative proportion of A_1 alleles in the population at time t .
$f(x; p, t)$	Solution of the forward or backward Kolmogorov equation corresponding to the initial condition $X(0)=p$.	$Y(\tau)$	In discrete-time models, the number of individuals in the population of allele-type A_1 at timestep τ .
h	Degree of dominance.	$Y(\tau)$	In discrete-time models with multiple alleles, the number of individuals in the population of allele-type $A_1, \dots, A_K$ at timestep τ .
$I_1(\cdot)$	Modified bessel function of the first kind of order 1.	α	The relative mutation bias in a 2-allele model.
K	In multi-allelic models, the number of allele types.	γ	In the diffusion limit, the scaled selection coefficient.
m_0	Current population size for the coalescent; Initial population size in the Bienaymé-Galton-Watson model.	$\Gamma(\cdot)$	The gamma function.
M	Haploid population size, or for diploid populations equivalent haploid population size $2N$.	$\delta(\cdot)$	Dirac delta function. See 14.
n_{sample}	The size of a randomly chosen sample of individuals in the population.	θ	In the diffusion limit, the total mutation rate.
N	Diploid population size.	$\hat{\theta}_W$	The Watterson estimator.
p_{ij}	In discrete-time models, Markov transition matrix from $Y(\tau)=i$ to $Y(\tau+1)=j$.	λ	Expected number of offspring per individual in the Bienaymé-Galton-Watson model.
q_{ab}	In the diffusion limit, the rate of mutations from allele A_a to allele A_b .	π_i	Probability that allele A_1 fixes given $Y(0)=i$.
Q	In the diffusion limit with multiple alleles, the instantaneous rate matrix, whose elements are q_{ab} .	σ^2	Variance of the number of offspring per individual in the Bienaymé-Galton-Watson model.
s	Selection coefficient.	τ	Discrete time steps in Wright-Fisher and Bienaymé-Galton-Watson models.
S	The proportion of genomic sites which are segregating.	τ_C	The coalescent time in generations of two randomly chosen individuals in a population.
$\mathcal{S}$	The $(K-1)$ -dimensional simplex.	$\bar{\tau}(i)$	Expected time for allele A_1 to fix conditional on $Y(0)=i$.
t	Continuum time in the diffusion limit.	$\bar{\tau}^*(i)$	Expected time for allele A_1 to fix conditional on A_1 fixing and $Y(0)=i$.
T_i	The inter-coalescence time.	Ω_Z	The range of a random variable Z .
u_{ab}	In discrete-time models, the probability of allele A_a mutating to allele A_b in one generation.		

Introduction

If we were to zoom in on a multiple alignment of one of our chromosomes across the entire human population we might see something like [Fig. 1](#). Assuming it is not an X or Y, every individual has two copies of the chromosome. At first sight the sequence appears to be identical across the population. However we would soon notice certain isolated points called *single nucleotide polymorphisms* (SNPs) which have been highlighted by vertical bars in the figure. At most SNPs two possible letters are observed, for instance A and T in the left hand SNP, and C and T in the right hand SNP in [Fig. 1](#). The two possible letters are an example of what are referred to as *alleles*. Very occasionally three-allele SNPs occur ([Cao et al., 2015](#)), while four-allele SNPs are extremely rare indeed ([Phillips et al., 2015](#)). Sequencing of the human genome has revealed in excess of 10 million SNPs ([1000 Genomes Project Consortium, 2010](#); [Shen et al., 2013](#)), at an average separation of about 300 bases, or, to put it another way roughly 1 in 300 genomic sites on average is observed to be a SNP. Furthermore, as the number of individuals sequenced increases, so does the reported density of SNPs increase as more sites are revealed to be SNPs. SNPs occur at higher density in non-protein-coding regions than in coding regions. SNPs are the most common type of sequence variation, estimated to account for 90% of all sequence variation.

Before proceeding, a word about terminology is in order. The word allele introduced above is generically used in population genetics to mean any one of a number of alternate forms of a genetic locus. For instance, if a locus contains n SNPs with two

Fig. 1 A small portion of a multiple genomic alignment across the entire population showing a sample of ten individuals. Only one strand of the double helix is shown. The sequences are grouped into pairs to indicate that each individual has two copies of each chromosome. The single nucleotide polymorphisms, or SNPs, are highlighted.

alternate bases observed at each SNP, the 2^n possible patterns may be referred to as 2^n alleles. Many older texts use the word *gene* as a synonym for allele. We avoid this use here to avoid confusion with the more common use of the word in genomics, namely a protein-coding sequence of nucleotides. A more extensive discussion of various subclasses of allele can be found in the text by Gillespie (2004).

In addition to SNPs there are other genomic differences between individuals, such as the presence of copy number variations (CNVs). These occur when an extended region which may be anywhere from a kilobase to several megabases is repeated a number of times, the number of repeats varying from one individual to another. This variation accounts for roughly 5% to 10% of the human genome. Other forms of genetic variation include insertions and deletions of a single letter or of extended regions, and reversals of extended regions. Without genetic variations, people of a given sex would all look very similar to one another; in other words, we would all be clones.

As a general rule, each instance of genetic variation is caused by a copying error or mutation occurring in the germline in a single individual, which is passed on to future generations. Here the word *germline* refers to the lineage of cells which, as cells split, are passed on to the next generation. In the case of sexual reproduction, the germline comprises those sperm or eggs which contribute to the next generation and the lineage of cells from which they are descended, all the way back to the initial cell from which the individual developed, called the zygote. The vast majority of the estimated 10^{13} to 10^{14} cells in a human are of course not part of the germline. Population genetics is concerned with genetic differences across and within populations and the dynamics of how errors occurring in the germ lines of single individuals can in time propagate through an entire population to create the phenomenon we know as evolution.

In this article we will concentrate principally on SNPs and ignore other forms of genetic variation. Mathematical modelling of the propagation of SNPs through a population takes into account two processes: *genetic drift* and *selection*. Genetic drift is conceptually the more difficult of the two. It refers to the diffusion process by which an allele already present at a given SNP will become more or less prevalent in the population mainly as a result of variability in the number of offspring of each individual (Masel, 2011). In the next section we will look at the simplest a model of genetic drift, the Wright-Fisher model, which is traditionally used as a starting point from which to develop more detailed and realistic models of population genetics.

Selection refers to the force driving an allele frequency in one direction or the other as a result of the fitness conferred by the mutation from which the SNP arose. Many mutations are harmful and may for instance make it unlikely an individual will survive long enough to produce offspring. For such mutations the frequency of occurrences within the population of the mutant allele will be forced downwards over generations. Occasionally a mutation will occur which confers an advantage which makes the individual more fit to produce offspring, thus driving the allele frequency upwards over generations. Mutations which confer neither an advantage or a disadvantage, such as mutations in a redundant part of the genome, are called *neutral*. Selection is modelled mathematically by augmenting existing models of genetic drift. Mathematical models which take into account only drift and mutations and not selection are referred to as models of neutral evolution.

Naïvely one may think that for evolution to proceed from point mutations in single individuals in a large population, propagation of mutations must be assisted by positive selection: one would expect the probability of a random mutation in a single individual to drift through the entire population must be very small indeed. Surprisingly, we will see that this is not the case:

nucleotide substitutions can occur throughout an entire population through neutral evolution without the aid of positive selection, driven by nothing other than genetic drift.

The Wright-Fisher Model

The simplest and possibly the earliest serious mathematical model of population genetics, known as the Wright-Fisher (WF) model, is attributed to [Fisher \(1930\)](#) and [Wright \(1931\)](#), neither of whom published a clear definition of the model per se, though each did publish a number of consequences of the model. To begin with we will look at the simplest form, namely the two-allele WF model with genetic drift but not mutations or selection. We start with a number of assumptions:

Non-overlapping generations: Assume that evolution occurs over discrete timesteps $\tau=0, 1, 2, \dots$, so that the entire population is replaced by a new population each timestep.

Fixed population: Assume the population size N remains fixed, independent of τ .

Diploid population: Assume each individual has two copies of the genome.

Monoecious population: Assume each individual carries both male and female reproductive organs, so that mating can occur between two individuals or within one individual to produce offspring.

Random mating: Assume each individual is the offspring of two randomly and independently chosen parents from the previous generation. Since the population is monoecious, both parents may be the same individual.

This list of assumptions is highly restrictive, but does not rule out all species of life on earth. Annual plants complete their life cycle from germination to production of seed in one year and then die. Many trees, such as oaks, cedars and figs, are monoecious. In particular, sunflowers are both monoecious and annuals, and it would not be totally impossible to contrive a situation in which a sunflower crop's size is held more or less constant. In spite of these restrictions, its mathematical simplicity makes the WF model a very popular starting point for much of the published work in population genetics, even though the assumptions are clearly violated for most populations. Often one will encounter the concept of "effective population size", for which there seems to be no universally accepted unambiguous definition. Loosely speaking, it means the value to which the parameter N in an 'ideal' model with some or all of the above assumptions should be set in order to give correct results, depending on what characteristics one wants to calculate, when applied to a population for which the assumptions may not necessarily be appropriate. See Sections 1.6 and 3.7 of [Ewens \(2004\)](#) for a detailed discussion of this point.

Given the assumptions, it is more convenient mathematically to think in terms of a population of $M=2N$ copies of the genome, rather than a population of N diploid individuals. Equivalently, one may think of the model as applying to a haploid population with the following assumptions:

Non-overlapping generations: Assume that evolution occurs over discrete timesteps $\tau=0, 1, 2, \dots$, so that the entire population is replaced by a new population each timestep.

Fixed population: Assume the population size M remains fixed, independent of τ .

Haploid population: Assume each individual has one copy of the genome.

Random parents: Assume each individual is the offspring of one randomly and independently chosen parent.

Male ants, for instance, are haploid because they develop from unfertilised haploid eggs. Another example is mitochondrial DNA, which is normally only inherited from the mother in sexually reproducing species. The female portion of a population is therefore haploid with respect its mitochondrial genome.

Now consider a given locus within a genome at which there are two distinct alleles, A_1 and A_2 . Define the random variable $Y(\tau)$, whose range is $\Omega_{Y(\tau)} = \{0, 1, \dots, M\}$, to be the number of copies of allele A_1 within the (effective haploid) population of size $M=2N$. Under the assumption of fixed total population size and an assumption that every individual chromosome at timestep τ is equally likely to be the progenitor of this SNP in a given individual chromosome at timestep $\tau+1$, the number of A_1 alleles in the population at time $\tau+1$, given the number of A_1 alleles in the previous generation τ , follows a binomial distribution:

$$\text{Prob } (Y(\tau+1) = j | Y(\tau) = i) = p_{ij} \quad (1)$$

where

$$p_{ij} = \binom{M}{j} \left(\frac{i}{M}\right)^j \left(1 - \frac{i}{M}\right)^{M-j}, \quad i, j = 0, 1, \dots, M, \quad (2)$$

since each new offspring inherits either allele A_1 with probability i/M , or allele A_2 with probability $1 - i/M$. [Eqs. \(1\) and \(2\)](#) define the WF model without mutations or selection, that is, a model in which the only effect driving the dynamics is genetic drift.

This system is an example of a finite-state Markov chain, with states labelled $i=0, 1, \dots, M$ and transition matrix p_{ij} . [Eq. \(2\)](#) implies that

$$p_{0j} = \begin{cases} 1 & \text{if } j = 0 \\ 0 & \text{if } j = 1, \dots, M \end{cases}, \quad p_{Mj} = \begin{cases} 0 & \text{if } j = 0, \dots, M-1 \\ 1 & \text{if } j = M. \end{cases} \quad (3)$$

Thus $Y(\tau)=0$ and $Y(\tau)=M$ are absorbing states of the Markov chain. These two states correspond respectively to the cases where the entire population has allele A_2 or A_1 at the site in question, and no further change is allowed by the model. If $Y(\tau)=M$ eventuates, we say that A_1 has become *fixed* in the population, and when $Y(\tau)=0$ we say A_2 has become fixed. If $Y(\tau) \in \{1, 2, \dots, M-1\}$, neither allele is yet fixed, and the site in question is said to be a *segregating site*.

Probability of Fixation

So far we have not built into the model any mechanism for a site to become a segregating site in the first place. We will come to that later when we deal with mutations in the section Including Mutations in the Wright-Fisher Model. For the time being, consider the initial condition $Y(0)=i$ for some $i=0, \dots, M$ and ask the question: What is the probability that allele A_1 becomes fixed? We have

$$\begin{aligned} & \text{Prob}(A_1 \text{ becomes fixed} | Y(0) = i) \\ &= \text{Prob}(Y(\infty) = M | Y(0) = i) \\ &= \sum_{j=1}^M \text{Prob}(Y(\infty) = M | Y(1) = j) \text{Prob}(Y(1) = j | Y(0) = i). \end{aligned} \quad (4)$$

We also have boundary conditions

$$\text{Prob}(Y(\infty) = M | Y(0) = 0) = 0, \quad \text{Prob}(Y(\infty) = M | Y(0) = M) = 1, \quad (5)$$

since 0 and M are absorbing states. Defining

$$\pi_i = \text{Prob}(Y(\infty) = M | Y(\tau) = i), \quad (6)$$

which we note is independent of τ since a Markov chain has no memory of prior events, Eqs. (4) and (5) become

$$\pi_i = \sum_{j=0}^M p_{ij} \pi_j, \quad \pi_0 = 0, \quad \pi_M = 1. \quad (7)$$

One easily checks that the solution is

$$\text{Prob}(A_1 \text{ becomes fixed} | Y(0) = i) = \pi_i = \frac{i}{M}. \quad (8)$$

Similarly, replacing the boundary conditions with $\pi_0 = 1, \pi_M = 0$ gives

$$\text{Prob}(A_2 \text{ becomes fixed} | Y(0) = i) = 1 - \pi_i = 1 - \frac{i}{M}, \quad (9)$$

implying that either one allele or the other must become fixed (Or, more precisely, one allele or the other becomes fixed ‘almost surely’, which is statistical jargon for ‘there exist trajectories in state space which never become fixed, but the probability of such a trajectory occurring is zero’.).

To interpret this result, consider a mutation which occurs in one member of the population at $\tau=0$. Intuitively one might expect that, for large populations, it is highly unlikely a mutation could become fixed by pure chance without the aid of natural selection. The above calculation shows that the WF model predicts a $1/M$ probability that a mutation in a single individual will become fixed in the population due to random genetic drift only. For instance, Fig. 2 shows a numerical simulation of 300 trajectories of the WF model with a population $M=100$, and, as predicted, in roughly 1 in 100 cases the mutation has become fixed (One case has not fixed on either allele yet, but A_1 looks like dying out after coming very close to fixing). On the other hand, the rate at which such mutations occur anywhere in the genome is proportional to the population size M , so we arrive at the surprising result that, even without natural selection, the model predicts that random mutations can fix in a population at a rate which is approximately independent of population size.

Expected Time to Fixation

A second question suggested by Fig. 2 is: What is the expected time for an allele to fix in the WF model? Consider first the unconditional problem of fixation in either of the two absorbing states. Define $\bar{\tau}(i)$ to be the expected number of time steps before fixation at either 0 or M given the initial conditions $Y(0)=i$. For either of the cases $i=0$ or $i=M$ the answer is trivial, while for any other value of i we can write a difference equation based on a sum of conditional expectation values labelled by the first step,

$$\bar{\tau}(i) = \sum_{j=0}^M p_{ij} \bar{\tau}(j) + 1, \quad i = 1, \dots, M-1, \quad (10)$$

$$\bar{\tau}(0) = \bar{\tau}(M) = 0. \quad (11)$$

This equation does not admit a simple analytic solution. However, assuming M is large, we can obtain a good approximation to the solution by taking a continuum limit in time

$$t = \frac{\tau}{M}, \quad \delta t = \frac{1}{M}, \quad (12)$$

Fig. 2 Simulation of the WF model: 300 independent trajectories for a population of $M=100$ copies of the genome, with a mutant allele introduced into one member of the population at $\tau=0$. Trajectories for which the mutant allele has become fixed are shown in red.

while at the same time defining a rescaled continuous random variable

$$X(t) = \frac{1}{M} Y(\tau), \quad \Omega_{X(t)} = [0, 1], \quad (13)$$

equal to the fraction of the population with allele A_1 . In Eq. (10) we make the substitutions

$$x = \frac{i}{M}, \quad u = \frac{j}{M}, \quad \bar{t}(x) = \frac{1}{M} \bar{\tau}(i), \quad (14)$$

and set

$$\delta X = X(\delta t) - X(0) = \frac{1}{M} (Y(1) - Y(0)), \quad (15)$$

to obtain

$$\begin{aligned} \bar{t}(x) &= \int_0^1 \text{Prob}(X(\delta t) = u | X(0) = x) \bar{t}(u) du + \frac{1}{M} \\ &= \int_0^1 \text{Prob}(X(\delta t) = u | X(0) = x) \\ &\quad \times \left\{ \bar{t}(x) + (u-x) \bar{t}'(x) + \frac{1}{2} (u-x)^2 \bar{t}''(x) + \dots \right\} du + \delta t \\ &= \left\{ \bar{t}(x) + E(\delta X | X(0) = x) \bar{t}'(x) + \frac{1}{2} E(\delta X^2 | X(0) = x) \bar{t}''(x) + \dots \right\} + \delta t. \end{aligned} \quad (16)$$

Eq. (16) holds for any model scaled according to Eqs. (12) and (13) irrespective of the form of the transition matrix p_{ij} . For the WF model in particular, $Y(1) | (Y(0)=i) \sim \text{Bin}(M, i/M)$, so

$$\begin{aligned} E(\delta X | X(0) = x) &= \frac{1}{M} E(Y(1) - Y(0) | Y(0) = i) \\ &= \frac{1}{M} \{E(Y(1) | Y(0) = i) - i\} \\ &= \frac{1}{M} \left(M \times \frac{i}{M} - i \right) \\ &= 0, \end{aligned} \quad (17)$$

and

$$\begin{aligned} E(\delta X^2 | X(0) = x) &= \text{Var}(\delta X | X(0) = x) + E(\delta X | X(0) = x)^2 \\ &= \frac{1}{M^2} \text{Var}(Y(1) - Y(0) | Y(0) = i) + 0 \\ &= \frac{1}{M^2} \left\{ M \times \frac{i}{M} \times \left(1 - \frac{i}{M} \right) \right\} \\ &= x(1-x) \delta t. \end{aligned} \quad (18)$$

Similarly one can show

$$E(\delta X^k | X(0) = x) = o(\delta t), \quad \text{for } k = 3, 4, \dots \text{ as } \delta t \rightarrow 0. \quad (19)$$

Substituting back into Eq. (16) and tidying up gives the differential equation

$$\frac{1}{2}x(1-x)\bar{t}''(x) + 1 = 0, \quad (20)$$

and from Eq. (11) we have the boundary conditions

$$\bar{t}(0) = \bar{t}(1) = 0. \quad (21)$$

One easily checks that the solution is

$$\bar{t}(x) = -2 \{x \log x + (1-x) \log(1-x)\} \quad (22)$$

or

$$\bar{t}(i) \approx -2M \left\{ \frac{i}{M} \log \frac{i}{M} + \left(1 - \frac{i}{M}\right) \log \left(1 - \frac{i}{M}\right) \right\}. \quad (23)$$

For instance, a SNP with both alleles equally populated could be expected to fix in $\bar{t}(M/2) \approx 1.39M$ generations.

A more pertinent question relevant to evolution might be to ask the expected time to fixation for trajectories such as those highlighted in red in Fig. 2, where a newly arrived allele A_1 has managed to fix. To answer this question, consider a new random variable

$$Y^*(\tau) = Y(\tau) | (Y(\infty) = M), \quad \Omega_{Y^*} = 1, \dots, M, \quad (24)$$

equal to the number of individuals in the population with allele A_1 , conditioned on the restricted set of trajectories for which A_1 fixes. The corresponding Markov transition matrix is

$$\begin{aligned} p_{ij}^* &= \text{Prob}(Y(\tau+1) = j | Y(\tau) = i, Y(\infty) = M) \\ &= \frac{\text{Prob}(Y(\tau+1) = j, Y(\infty) = M | Y(\tau) = i)}{\text{Prob}(Y(\infty) = M | Y(\tau) = i)} \\ &= \frac{\text{Prob}(Y(\tau+1) = j | Y(\tau) = i) \text{Prob}(Y(\infty) = M | Y(\tau+1) = j)}{\text{Prob}(Y(\infty) = M | Y(\tau) = i)} \\ &= \frac{p_{ij}\pi_j}{\pi_i}, \quad i, j = 1, \dots, M \end{aligned} \quad (25)$$

where, in the third line, we have used the Markovian property that the trajectory $\tau \rightarrow \tau+1$ is independent of the trajectory $\tau+1 \rightarrow \infty$.

For the case of the WF model, it is straightforward to check that Eqs. (2), (8), and (25) imply

$$p_{ij}^* = \binom{M-1}{j-1} \left(\frac{i}{M}\right)^{j-1} \left(1 - \frac{i}{M}\right)^{M-j}, \quad i, j = 1, \dots, M, \quad (26)$$

and that consequently the random variable $Y^*(\tau+1) - 1$ conditioned on $Y^*(\tau) = i$ is binomial:

$$Y^*(\tau+1) | (Y^*(\tau) = i) \sim \text{Bin}(M-1, i/M) + 1. \quad (27)$$

Following the same line of reasoning as for the unrestricted case, we find that Eq. (16) also applies to an analogous set of starred variables defined by

$$X^*(t) = \frac{1}{M} Y^*(\tau), \quad \delta X^* = \frac{1}{M} (Y^*(1) - Y^*(0)), \quad \bar{t}^*(x) = \frac{1}{M} \bar{t}^*(i). \quad (28)$$

However, calculations analogous to Eqs. (17) and (18) now give

$$E(\delta X^* | X^*(0) = x) = (1-x) \delta t, \quad (29)$$

$$E(\delta X^{*2} | X^*(0) = x) = x(1-x) \delta t + O(\delta t^2), \quad (30)$$

leading to the differential equation

$$(1-x)\bar{t}^{*'}(x) + \frac{1}{2}x(1-x)\bar{t}^{*''}(x) + 1 = 0, \quad (31)$$

for the expected time to fixation conditional on A_1 fixing, $\bar{t}^*(x)$. The solution should also satisfy the boundary condition

$$\bar{t}^*(1) = 0, \quad (32)$$

and the symmetry condition

$$\begin{aligned} \bar{t}(x) &= \text{Prob}(X(\infty) = 1) \bar{t}^*(x) + \text{Prob}(X(\infty) = 0) \bar{t}^{**}(x) \\ &= x \bar{t}^*(x) + (1-x) \bar{t}^{**}(1-x), \end{aligned} \quad (33)$$

where $\bar{t}(x)$ is given by Eq. (22) and $\bar{t}^{**}(x)$ is the expected time to fixation conditional on A_2 fixing. The required solution is

$$\bar{t}^*(x) = -\frac{2}{x} (1-x) \log(1-x), \quad (34)$$

or

$$\bar{\tau}^*(i) = -\frac{2M^2}{i} \left(1 - \frac{i}{M}\right) \log \left(1 - \frac{i}{M}\right). \quad (35)$$

If a mutation is introduced into a single member of a large population at $\tau=0$ and the mutation fixes, Eq. (35) says that the expected time to fix is approximately $\bar{\tau}^*(1) \approx 2M(1 + O(1/M))$. The red trajectories in Fig. 2 are broadly in agreement with this result.

Including Mutations in the Wright-Fisher Model

So far mutations have only been included in the model as an ad hoc specification of initial conditions. In this section we introduce mutations dynamically in a way which can be generalised to incorporate instantaneous rate matrices for multiple alleles in the section Multiple Alleles.

Consider again a locus in which only two alleles are present, or equivalently, assume a site in a simplified model genome in which the genomic alphabet only consists of two letters, A_1 and A_2 . Returning to the assumptions of the WF model, we add one more assumption:

Random mutation: Following the germline over one generation, a locus occupied by an A_1 allele at the initial time of inheritance has a probability u_{12} of mutating to A_2 before reproductive maturity, and a genomic site initially occupied by an A_2 allele has a probability u_{21} of mutating to A_1 before reproductive maturity.

By ‘reproductive maturity’ we mean the point at which the genomic information is passed onto the next generation. In principle any values in the range $0 \leq u_{12}, u_{21} \leq 1$ are allowed by the mathematics, though in practice the mutation rates per generation are typically very small.

Now interpret the random variable $Y(\tau)$ as the number of copies of allele A_1 within the population at birth. Conditioning on the event $Y(\tau)=i$ for some $i=0, \dots, M$, the following four events are possible in any one member of the population:

- E1: The locus inherits allele A_1 and does not mutate;
- E2: The locus inherits allele A_1 and mutates to A_2 ;
- E3: The locus inherits allele A_2 and does not mutate;
- E4: The locus inherits allele A_2 and mutates to A_1 .

Then the probability the locus will be occupied by allele A_1 at maturity, given that $Y(\tau)=i$ at birth, is

$$\psi(i) = \text{Prob}(E_1) + \text{Prob}(E_4) = \frac{i}{M}(1 - u_{12}) + \left(1 - \frac{i}{M}\right)u_{21} \quad (36)$$

and the probability it will be occupied by allele A_2 is

$$1 - \psi(i) = \text{Prob}(E_2) + \text{Prob}(E_3) = \frac{i}{M}u_{12} + \left(1 - \frac{i}{M}\right)(1 - u_{21}) \quad (37)$$

Again we see that $Y(\tau+1)|Y(\tau)=i$ is a binomial random variable, but the Markov transition matrix defined by Eq. (1) is modified from Eq. (2) to

$$p_{ij} = \binom{M}{j} \psi(i)^j (1 - \psi(i))^{M-j}, \quad i, j = 0, 1, \dots, M, \quad (38)$$

where $\psi(i)$ is defined above.

One can check that if u_{12} and u_{21} are both non-zero, the Markov chain has no absorbing states; if $u_{12}=0$ and $u_{21}>0$, $Y(\tau)=M$ is the only absorbing state, implying that A_1 must fix (almost surely); and if $u_{21}=0$ and $u_{12}>0$, $Y(\tau)=0$ is the only absorbing state, implying that A_2 must fix (almost surely).

Fig. 3 shows a simulation of a trajectory of this model with parameter values $M=100$, $u_{12}=0.0005$ and $u_{21}=0.0003$ chosen to demonstrate the behaviour. In most real-world scenarios populations are much higher (in studies of humans effective population sizes of $\sim 10^5$ are often used) and mutation rates much lower (human genomic mutation rates at a neutral site may typically be $\sim 10^{-8}$ per individual per generation). Nevertheless, we note the important features that most of the time a genomic site is not segregating (i.e. $Y(\tau)=0$ or M), and the transition between the two almost-fixed states $Y(\tau)=0$ and M occurs over a time roughly the same order of magnitude as the fixation time $\bar{\tau}^*(1) \approx 2M$ obtained for the simpler model of Section Expected Time to Fixation. A similar effect is explained by Vogl and Bergman (2015) in the context of the 2-allele Moran model as a strong dominance of genetic drift over mutations for polymorphic sites.

The rate at which new alleles fix throughout a population is called the *substitution rate*. For the current WF model it can be estimated as follows. For a given site which is currently non-segregating of type A_1 , the number of individuals out of a population of size M who mutate to type A_2 in a given generation is Poisson with parameter $u_{12}M$. Thus the probability that at least one mutation occurs is $1 - e^{-u_{12}M} \approx u_{12}M$ for $u_{12}M \ll 1$. Thus the expected time between ‘attempted’ mutations in a population of size

Fig. 3 Simulation of a single trajectory of the WF model with mutations. The parameters are: population of $M=100$ copies of the genome, mutation rate A_1 to A_2 of $u_{12}=0.0005$ per generation and A_2 to A_1 of $u_{21}=0.0003$ per generation. $Y(\tau)$ is the number of A_1 alleles in the population. As described in the text, the expected substitution time before an A_2 allele fixes given that a site is currently fixed at A_1 , is approximately $1/u_{12}$; the expected A_2 to A_1 substitution time is approximately $1/u_{21}$, and the expected time the substitution takes to occur is $2M$.

Fig. 4 Stationary distribution of WF model with mutations. Parameters are the same as for Fig. 3. The right-hand panel is the same plot on a logarithmic scale.

M is $1/(u_{12}M)$. Of those attempted mutations, Eqs. (8) and (9) tell us that a fraction $1/M$ will fix throughout the population, assuming fixation is driven mainly by drift for low mutation rates. Thus the expected time to the next time allele A_2 fixes throughout the population at the site in question is $M \times 1/(u_{12}M) = 1/u_{12}$, and the population's substitution rate for A_1 to A_2 is u_{12} . Similarly the substitution rate for A_2 to A_1 is u_{21} . In summary, for the WF model with low mutation rates, the population's substitution rate matches the genomic mutation rate. To put it another way, if we consider the genomic alphabet to consist of only 2 letters instead of 4, the instantaneous rate matrix appropriate to, say, maximum likelihood estimates of phylogenetic trees, is

$$U = \begin{pmatrix} -u_{12} & u_{12} \\ u_{21} & -u_{21} \end{pmatrix} \quad (39)$$

provided time from one generation to the next is used as the unit of time.

Another way to interpret the two-allele WF model with mutations is to consider the stationary distribution of the Markov transition matrix Eq. (38), namely $\text{Prob}(Y(\infty)=i)$. The numerically determined distribution is plotted in Fig. 4 for the same set of parameters as Fig. 3. Recall that the model can be thought of as a toy model of a genomic site corresponding to a world in which the genomic alphabet has only two possible nucleotides, A_1 and A_2 . If we consider the genome to be a set of independent genomic sites which have been evolving according to the WF model for a considerable time, this distribution can be thought of as the

distribution of allele frequencies throughout the genome. Most genomic sites are not segregating, but contribute to the spike in the left hand plot at $i=100$ if the site is occupied by nucleotide A_1 or the spike at $i=0$ if the site is occupied by nucleotide A_2 . The remaining vertical bars in the plot correspond to the segregating sites, or SNPs, the height of the bar being the proportion of sites in a large genome at which the allele A_1 occurs in a fraction i/M of the population. This distribution is called the *site frequency spectrum* (SFS). The SFS is important because it is directly observable from sequencing data, and can, in principle, enable estimation of mutation rates under the assumption of a given population genetics model. In a later section we show how to solve for the SFS for WF type models in the continuum limit $M \rightarrow \infty$.

Before moving on, we make the observation in passing that the model we have considered is of course a very crude approximation to the observed SFS of any real genome, even if the assumptions of the Wright-Fisher Model hold and we restrict ourselves to parts of the genome undergoing neutral evolution, that is, evolution without selection. One important problem is that genetic drift is an extremely slow process for large populations, calling into question any assumption of stationarity (Gillespie, 2004, pp. 25–26). Another problem is that sites are not independent to the extent that mutation rates are known to depend on neighbouring bases (Aggarwala and Voight, 2016; Zhu *et al.*, 2017). Models which include neighbouring-base context dependence are very difficult to make any progress with analytically, because the neighbouring bases themselves mutate on the same timescale. Consequently, analytic results for population genetics models which include context dependence are almost completely absent from the scientific literature.

Including Selection in the Wright-Fisher Model

Return now to the set of assumptions set out in the section. The Wright-Fisher Model leading to the WF model for a diploid population. Note that each individual in the population can be any one of three *genotypes*: A_1A_1 , A_1A_2 and A_2A_2 . Suppose we add one extra assumption:

Selection: Assume that the probability an individual survives to maturity and therefore has the potential to procreate is dependent on the genotype of the individual. This probability is known as the *fitness* of the genotype.

A common convention is to specify the ratios of relative fitnesses of the three genotypes, without explicit regard to normalisation. In order to specify three relative fitnesses, two parameters are needed. Here we will adopt the convention used in Equation (1.2b) of Ewens (2004) and Section 5.3 of Etheridge (2011) that the relative fitnesses of the three genotypes are in the proportions

$$1 + s : 1 + hs : 1 \quad (40)$$

where s is called the *selection coefficient* and h is called the *degree of dominance*: if h is close to 1, A_1 is dominant to A_2 in fitness; if h is close to zero, A_2 is dominant to A_1 in fitness; and if $h = \frac{1}{2}$ there is no dominance in fitness.

If, at the beginning of generation τ , the number of A_1 alleles in a population of size $M=2N$ is $Y(\tau)=i \in \{0, \dots, M\}$, then the assumption of random mating implies that the relative proportion of new-born genotypes A_1A_1 , A_1A_2 and A_2A_2 is

$$i^2 : 2i(M-i) : (M-i)^2. \quad (41)$$

This set of relative proportions is known as *Hardy-Weinberg equilibrium* (HWE) (Hardy, 1908; Stern, 1943). The relative proportion of surviving mature genotypes in the population is then

$$i^2(1+s) : 2i(M-i)(1+hs) : (M-i)^2 \quad (42)$$

The number of A_1 alleles present in the newborn population at time $\tau+1$, given that there were i type- A_1 alleles in the newborn population at time τ , that is $Y(\tau+1)|(Y(\tau)=i)$, will once again be a binomial random variable with Markov transition matrix of the form

$$p_{ij} = \binom{M}{j} \eta(i)^j (1-\eta(i))^{M-j}, \quad i, j = 0, 1, \dots, M. \quad (43)$$

Here $\eta(i)$ is the probability that a given newborn allele will be A_1 . Note that random mating of the previous mature generation ensures that the $\eta(i)$ are inherited from genotypes of the previous mature generation who are in the relative ratios

$$\eta(i)^2 : 2\eta(i)(1-\eta(i)) : (1-\eta(i))^2. \quad (44)$$

Comparing Eqs. (42) and (44) we have

$$\eta(i)^2 = \frac{i^2(1+s)}{w}, \quad 2\eta(i)(1-\eta(i)) = \frac{2i(M-i)(1+hs)}{w}, \quad (45)$$

where $w = i^2(1+s) + 2i(M-i)(1+hs) + (M-i)^2$. Thus

$$\begin{aligned} \eta(i) &= \eta(i)^2 + \eta(i)(1-\eta(i)) \\ &= \frac{i^2(1+s) + i(M-i)(1+hs)}{i^2(1+s) + 2i(M-i)(1+hs) + (M-i)^2}. \end{aligned} \quad (46)$$

Thus, Eqs. (43) and (46) define the Markov transition matrix of the 2-allele WF model for a randomly-mating diploid population with selection, but no mutation.

Including selection in the WF model for a haploid population is somewhat simpler. In this case there is no distinction between allele types and genotypes. Without loss of generality we can define relative fitnesses of the two allele types A_1 and A_2 in terms of a single parameter s as

$$1 + \frac{1}{2}s : 1. \quad (47)$$

If at time step τ the number of newborn A_1 alleles is $Y(\tau)=i$ and the number of newborn A_2 alleles is $M-i$, then the relative probabilities of an individual inheriting an A_1 or A_2 allele are

$$i(1 + \frac{1}{2}s) : M - i \quad (48)$$

implying that the probability of a newborn individual at time step $\tau+1$ being A_1 is

$$\eta(i) = \frac{i(1 + \frac{1}{2}s)}{i(1 + \frac{1}{2}s) + M - i}. \quad (49)$$

Eqs. (43) and (49) define the Markov transition matrix of the 2-allele WF model for a haploid population with selection, but no mutation.

Diffusion Limit and the Forward Kolmogorov Equation

Although no analytic solution exists for the SFS shown in Fig. 4 corresponding to the stationary distribution of the WF model with mutations, Eq. (38), or for the analogous stationary distribution of the WF model with selection, Eq (43), very close approximations can be found in the form of exact stationary distributions of a continuum model constructed by taking the so-called *diffusion limit* $M \rightarrow \infty$. This limit involves constructing a partial differential equation known variously as the *forward Kolmogorov equation* or *Fokker-Planck equation*, which describes the time evolution of a probability density over allele frequencies.

More generally, the Fokker-Planck equation was published by Adriaan Fokker in 1914 and Max Planck in 1917 in the context of studying the velocity distribution of particles undergoing Brownian motion. The forward Kolmogorov equation is equivalent and was published by Andrei Kolmogorov in 1931 in the context of a more general study of the continuous-time diffusion limit of Markov processes. The influence of the diffusion limit and the forward Kolmogorov equation in population genetics is generally attributed to Kimura (1964) who obtained diffusion limit solutions to a number of models including the neutral WF model (Kimura, 1955a) and the WF model with selection (Kimura, 1955b).

Appendix A contains a derivation of the forward Kolmogorov equation for a generic population genetics model based on a discrete time finite state Markov chain. The derivation given is for a genomic site at which two alleles A_1 and A_2 are possible in a population of fixed size M . We assume also that we are given a time-independent Markov transition matrix

$$p_{ij} = \text{Prob}(Y(\tau+1) = j | Y(\tau) = i), \quad i, j = 0, \dots, M, \quad (50)$$

where $Y(\tau)$ are the number of A_1 alleles present in the population at discrete times $\tau=0,1,2,\dots$,

With the intention of taking the limit $M \rightarrow \infty$, consider the substitutions which proved useful above for calculating fixation times:

$$t = \frac{\tau}{M}, \quad \delta t = \frac{1}{M}, \quad X(t) = \frac{1}{M} Y(\tau). \quad (51)$$

After taking the limit $M \rightarrow \infty$, t becomes a continuous time variable over the interval $[0, \infty)$ and the fraction $X(t)$ of the population with allele A_1 becomes a continuous random variable with range $\Omega_X = [0, 1]$. The aim of the forward Kolmogorov equation is to describe the evolution of the probability density $f(x; p, t)$ corresponding to $X(t)$, conditional on an initial condition $X(0) = p$, that is,

$$f(x; p, t) dx = \text{Prob}(x \leq X(t) < x + dx | X(0) = p), \quad 0 \leq x, p \leq 1, \quad t > 0. \quad (52)$$

In order to obtain a sensible continuum limit from Eq. (51), there is an extra requirement that the moments of the random variable $\delta X(t) = X(t + \delta t) - X(t)$ must be of the form

$$\begin{aligned} E[\delta X(t) | X(t) = u] &= a(u) \delta t + o(\delta t) \\ E[(\delta X(t))^2 | X(t) = u] &= b(u) \delta t + o(\delta t) \\ E[(\delta X(t))^k | X(t) = u] &= o(\delta t), \quad k = 3, 4, \dots, \end{aligned} \quad (53)$$

as $\delta t \rightarrow 0$ for finite, well behaved functions $a(u)$ and $b(u)$ defined for $0 \leq u \leq 1$. We have already seen this condition satisfied for the WF model by Eqs. (17) to (19) and the WF model conditioned on fixing allele A_1 by Eqs. (29) and (30), and below we will also see it satisfied for WF model with mutations and selection. For some population genetics models such as the Moran model

described later in the chapter, the continuum limit is defined differently to Eq. (51), in which case Eq. (53) must be adjusted accordingly.

With this machinery in place it is shown in Appendix A that the forward Kolmogorov equation takes the form

$$\frac{\partial f(x; p, t)}{\partial t} = -\frac{\partial}{\partial x} [a(x)f(x; p, t)] + \frac{1}{2} \frac{\partial^2}{\partial x^2} [b(x)f(x; p, t)]. \quad (54)$$

For any specific population genetics model, the functions $a(x)$ and $b(x)$ are determined from the Markov transition matrix p_{ij} .

The Continuum Wright-Fisher Model With Mutations

We now return to the WF model with 2-way mutations derived earlier. Including Mutations in the Wright-Fisher Model. To determine the functions $a(x)$ and $b(x)$ in the forward Kolmogorov equation, we need to apply the continuum limit defined by Eq. (51). Because the mutation rates u_{12} and u_{21} are defined as probabilities of mutation per generation, and the generation time $\delta t = 1/M$ becomes infinitesimal in the limit $M \rightarrow \infty$, rescaled mutation rates with respect to the continuum time t are needed. Accordingly we set

$$q_{12} = Mu_{12}, \quad q_{21} = Mu_{21}. \quad (55)$$

Note from the argument leading to Eq. (39) that when $q_{12}, q_{21} < 1$, the matrix

$$Q = \begin{pmatrix} -q_{12} & q_{12} \\ q_{21} & -q_{21} \end{pmatrix}, \quad (56)$$

is also the instantaneous rate matrix with respect to the continuum time t for allele substitution throughout the population.

For the transition matrix Eq. (38),

$$\begin{aligned} E[\delta X(t) | X(t) = x] &= \frac{1}{M} E[Y(\tau + 1) - Y(\tau) | Y(\tau) = i] \\ &= \frac{1}{M} (M\psi(i) - i) \\ &= -\frac{i}{M} u_{12} + \left(1 - \frac{i}{M}\right) u_{21} \\ &= [-q_{12}x + q_{21}(1-x)]\delta t. \end{aligned} \quad (57)$$

Comparing with Eq. (53) then gives

$$a(x) = -q_{12}x + q_{21}(1-x), \quad (58)$$

while a similar calculation using the variance gives

$$b(x) = x(1-x). \quad (59)$$

We are now in a position to determine the stationary distribution of the continuum limit of the WF model with two-way mutations. Substituting $a(x)$ and $b(x)$ into Eq. (54), setting $\partial f/\partial t = 0$ and integrating once gives the ordinary differential equation

$$[q_{12}x - q_{21}(1-x)]f(x) + \frac{1}{2} \frac{d}{dx} [x(1-x)f(x)] = \text{const.} \quad (60)$$

It is possible to show that the constant of integration on the right hand side corresponds to a flux of probability across the boundaries at $x=0$ and $x=1$, which must be zero. Then it is straightforward to check that the function

$$f(x) = \frac{1}{B(2q_{21}, 2q_{12})} x^{2q_{21}-1} (1-x)^{2q_{12}-1} \quad 0 \leq x \leq 1, \quad (61)$$

is a solution to the ordinary differential equation and is thus the required stationary distribution of the forward Kolmogorov equation. Here the prefactor, which is written in terms of the beta function, whose definition is (Abramowitz *et al.*, 1972)

$$B(z_1, z_2) = \int_0^1 x^{z_1-1} (1-x)^{z_2-1} dx, \quad z_1, z_2 > 0, \quad (62)$$

ensures that the probability density function $f(x)$ has the correct normalisation, i.e., $\int_0^1 f(x) dx = 1$. This distribution is the well known beta distribution, and was first identified as the stationary distribution in the presence of two-way mutations by Wright (1931), without explicit reference to the forward Kolmogorov equation.

Fig. 5 shows the SFS for the example in Fig. 4 reproduced with the stationary solution to the continuum theory, Eq. (61), superimposed. The horizontal and vertical axes have been rescaled by factors of $1/M$ and M respectively in order to make the comparison and the parameters $2q_{12}=0.05$ and $2q_{21}=0.03$ calculated from Eq. (55). To compare with the SFS at $i=0$ and M ,

Fig. 5 The SFS computed in Fig. 4 for a WF model with two-way mutation for a finite population M , rescaled to the continuum parameter $x=i/M$ (black), and the continuum stationary solution Eq. (61) to the forward Kolmogorov equation with corresponding parameters $2q_{12}=0.05$ and $2q_{21}=0.03$ (red). The red plus signs at $x=0$ and $x=1$ are computed from Eqs. (63) and (64).

contributions from the singularities in $f(x)$ at $x=0$ and $x=1$ are estimated as

$$\begin{aligned} \text{Prob}(Y(\infty) = 0) &\approx \int_0^{1/M} f(x) dx \\ &\approx \frac{1}{B(2q_{21}, 2q_{12})} \int_0^{1/M} x^{2q_{21}-1} dx \\ &= \frac{M^{-2q_{21}}}{2q_{21}B(2q_{21}, 2q_{12})}, \end{aligned} \quad (63)$$

and

$$\begin{aligned} \text{Prob}(Y(\infty) = 1) &\approx \int_{1-1/M}^1 f(x) dx \\ &\approx \frac{1}{B(2q_{21}, 2q_{12})} \int_{1-1/M}^1 (1-x)^{2q_{12}-1} dx \\ &= \frac{M^{-2q_{12}}}{2q_{12}B(2q_{21}, 2q_{12})}. \end{aligned} \quad (64)$$

Clearly, the agreement in Fig. 5 is excellent even at this moderate value of M , indicating that the continuum limit $M \rightarrow \infty$ is reached rapidly.

In biologically relevant situations it often happens that $q_{12}, q_{21} < 1$. In this case a useful approximation to the stationary distribution is

$$f(x) \approx \frac{2q_{12}q_{21}}{q_{12} + q_{21}} \left(\frac{1}{x} + \frac{1}{1-x} \right), \quad (65)$$

valid for $q_{21} \log x < 1$ and $q_{12} \log(1-x) < 1$, with the terminal spikes approximated by

$$\begin{aligned} \text{Prob}(Y(\infty) = 0) &\approx \frac{q_{12}}{q_{12} + q_{21}} (1 - 2q_{21} \log M), \\ \text{Prob}(Y(\infty) = 1) &\approx \frac{q_{21}}{q_{12} + q_{21}} (1 - 2q_{12} \log M). \end{aligned} \quad (66)$$

These approximations are a consequence of the property of the beta function that

$$\frac{1}{B(\varepsilon, \eta)} = \frac{\varepsilon\eta}{\varepsilon + \eta} (1 + O(\varepsilon) + O(\eta)) \quad \text{as } \varepsilon, \eta \rightarrow 0. \quad (67)$$

The function Eq. (65) is easily seen to be a solution to Eq. (60) with q_{12} and q_{21} set to zero. The physical import of this approximation is therefore that the dynamics is driven by drift, and not mutation, over most of the range of x , and that the role of mutations is to set the normalisation of Eq. (60) via the influence of boundary effects at x close to 0 and 1. This interpretation is described in the context of the Moran model with mutations and selection by Vogl and Bergman (2015) who introduce the terminology *boundary-mutation model* to refer to the low mutation rate approximation.

The Continuum Wright-Fisher Model With Mutations and Selection

Analogous to the continuous time mutation rates Eq. (55), we define a continuous-time selection coefficient

$$\gamma = Ms, \quad (68)$$

where s was defined by Eqs. (40) and (47) for diploid and haploid populations respectively. A calculation analogous to Eq. (57) using the transition matrix for WF with selection, Eqs. (43), (46) and (49), yields the first order derivative coefficient

$$a(x) = \begin{cases} \gamma x(1-x)[x + h(1-2x)] & \text{(diploid),} \\ \frac{1}{2}\gamma x(1-x) & \text{(haploid),} \end{cases} \quad (69)$$

in the forward Kolmogorov equation, while the second order derivative coefficient $b(x)$ in Eq. (59) remains unchanged.

Note that forward Kolmogorov equation for the diploid case of no-dominance, $h = \frac{1}{2}$, is identical to haploid equation. If both mutations and selection are included, the no-dominance diploid or haploid forward Kolmogorov equation is

$$\begin{aligned} \frac{\partial f(x; p, t)}{\partial t} = & -\frac{\partial}{\partial x} \left[\left(\frac{1}{2}\gamma x(1-x) - q_{12}x + q_{21}(1-x) \right) f(x; p, t) \right] \\ & + \frac{1}{2} \frac{\partial^2}{\partial x^2} [x(1-x)f(x; p, t)]. \end{aligned} \quad (70)$$

The stationary solution to this equation is

$$f(x) = Cx^{2q_{21}-1}(1-x)^{2q_{12}-1}e^{\gamma x}, \quad (71)$$

where the constant C is chosen to ensure $\int_0^1 f(x) dx = 1$.

A complete time dependent solution to Eq. (70) for the case of selection but no mutation (i.e. $q_{12}=q_{21}=0$) is derived in Section 8.6 of Crow and Kimura (1970). The solution is highly complex, however it is relatively easy to derive the result that, given an initial relative frequency p , allele A_1 will fix with probability (Waxman, 2011; Ewens, 2004, Sections 4.3 and 5.3)

$$\text{Prob}(X(\infty) = 1 | X(0) = p) = \frac{1 - e^{-\gamma p}}{1 - e^{-\gamma}}. \quad (72)$$

Estimation of Mutation Rates

We return now to the stationary solution to the diffusion limit WF model with neutral mutations, namely Eq. (61), and address the problem of estimating mutation rates from sampled SNP data. In the following it will prove useful to use an alternate parameterisation similar to that used by Vogl (2014), and set

$$\theta = q_{12} + q_{21}, \quad \alpha = \frac{q_{12}}{q_{12} + q_{21}}. \quad (73)$$

The parameter θ is the scaled total mutation rate and the parameter α is a measure of the relative bias between A_1 to A_2 mutations and A_2 to A_1 mutations. In terms of the newly defined parameters, Eq. (61) becomes

$$f(x) = \frac{1}{B(2(1-\alpha)\theta, 2\alpha\theta)} x^{2(1-\alpha)\theta-1} (1-x)^{2\alpha\theta-1}, \quad 0 \leq x \leq 1. \quad (74)$$

Generally one expects an effective population to be considerably larger than that of the toy examples considered in the numerical simulations Figs. 2 to 5, and if stationarity is assumed it should be possible in principle to estimate the continuum limit parameters such as θ and α from an observed SFS. However it is important to realise that the distribution $f(x)$ of the SFS is not observed directly, simply because a census of the genomic makeup an entire population is not practical. Instead, biologists will sequence the genomes of a sample of the population, which is ideally randomly chosen.

Maximum Likelihood Estimator

Suppose we assume a sample of n_{sample} individual chromosomes across n_{site} independent genomic sites, each assumed chosen to be a site not susceptible to selective pressures. We also assume the genome to have evolved so as to represent the stationary state of the simplified model in which the genome consists only of letters A_1 and A_2 from a 2-letter alphabet, and that all the assumptions leading to the neutral WF model with two-way mutations hold.

In this case the data will consist of a set of i.i.d. random numbers $U_1, U_2, \dots, U_{n_{\text{site}}}$ of type A_1 alleles, each taking a value in the set $\{0, 1, \dots, n_{\text{sample}}\}$, observed at the n_{site} genomic sites. At any given site j , conditional on an (unobserved) underlying population fraction x of A_1 -type alleles at that site, each U_j will be a binomial random variable:

$$U_j | (X = x) \sim \text{bin}(n_{\text{sample}}, x), \quad (75)$$

where X has the beta distribution, Eq. (74). Thus the unconditional distribution of each U_j is

$$\begin{aligned}
 \text{Prob}(U_j = u) &= \int_0^1 \text{Prob}(U_j = u|X = x)f(x) dx \\
 &= \int_0^1 \binom{n_{\text{sample}}}{u} x^u (1-x)^{n_{\text{sample}}-u} \times \frac{x^{2(1-\alpha)\theta-1} (1-x)^{2\alpha\theta-1}}{B(2(1-\alpha)\theta, 2\alpha\theta)} dx \\
 &= \binom{n_{\text{sample}}}{u} \frac{1}{B(2(1-\alpha)\theta, 2\alpha\theta)} \\
 &\quad \times \int_0^1 x^{u+2(1-\alpha)\theta-1} (1-x)^{n_{\text{sample}}-u+2\alpha\theta-1} dx \\
 &= \binom{n_{\text{sample}}}{u} \frac{B(u+2(1-\alpha)\theta, n_{\text{sample}}-u+2\alpha\theta)}{B(2(1-\alpha)\theta, 2\alpha\theta)},
 \end{aligned} \tag{76}$$

for $u=0, \dots, n_{\text{sample}}$. Eq. (76) is the probability function of the beta-binomial distribution (Johnson *et al.*, 1993). This is a 3-parameter family of discrete distributions whose generic probability mass function takes the form

$$P_U(u; n, a, b) = \binom{n}{u} \frac{B(u+a, n-u+b)}{B(a, b)}, \quad u = 0, \dots, n, \tag{77}$$

where n is a non-negative integer and a and b are positive real numbers.

Given the dataset described above, the parameters θ and α can be estimated numerically via a maximum likelihood calculation. In this case one would maximize the log likelihood

$$L(\theta, \alpha | u_1, \dots, u_{n_{\text{site}}}) = \sum_{j=1}^{n_{\text{site}}} \log P_U(u_j; n_{\text{sample}}, 2(1-\alpha)\theta, 2\alpha\theta), \tag{78}$$

with respect to θ and α , where $u_1, \dots, u_{n_{\text{site}}}$ are the observed counts of type- A_1 alleles at each site. Vogl (2014) has developed an expectation-maximisation algorithm for performing this maximisation.

Relationship to the Watterson Estimator

A commonly encountered estimator of the scaled total mutation rate θ , used when $\theta \ll 1$ and $\alpha = \frac{1}{2}$, is the *Watterson estimator* (Watterson, 1975). In the language of our current analysis it states that, if n_{sample} genomes are sampled, and the proportion of sites which are observed to be segregating is S , then

$$\hat{\theta}_W = \frac{S}{\sum_{i=1}^{n_{\text{sample}}-1} (1/i)}, \tag{79}$$

is an unbiased estimate of θ . A site is said to be segregating if more than one allele is observed at that site (i.e. it is observed to be a SNP on the basis of a sample of size n_{sample}). An demonstration that the Watterson estimator is unbiased will be given from the point of view of the coalescent in the section The Kingman Coalescent and the Watterson Estimator.

By carrying out an expansion of the beta-binomial distribution in the small parameter θ , Vogl (2014) has obtained maximum likelihood estimators which generalise Watterson's result to the case $\alpha \neq \frac{1}{2}$. Vogl's estimators are

$$\hat{\theta}_V = \frac{S}{\sum_{i=1}^{n_{\text{sample}}-1} (1/i)}, \quad \hat{\alpha}_V = S_2 + \frac{1}{2}S, \tag{80}$$

where S is the proportion of sites that are segregating and S_2 is the proportion of sites that are non-segregating with the observed allele being A_2 . Here $\hat{\theta}_V$ is an unbiased, maximum likelihood estimator of the quantity

$$\vartheta = 4\alpha(1-\alpha)\theta, \tag{81}$$

which reduces to θ when $\alpha = \frac{1}{2}$.

Below we give a brief proof that $\hat{\theta}_V$ is unbiased. Note first that S is an unbiased estimator of the probability that a site chosen at random from a very large number of independent sites is observed to be segregating. Equivalently, $E[S]$ is the probability that the random variable U_j in the distribution Eq. (76) is neither 1 or n_{sample} . Thus to demonstrate that $\hat{\theta}_V$ is indeed an unbiased estimator of ϑ it suffices to show that

$$1 - \text{Prob}(U_j = 0) - \text{Prob}(U_j = n_{\text{sample}}) = 4\alpha(1-\alpha)\theta \sum_{i=1}^{n_{\text{sample}}-1} \frac{1}{i}, \quad \text{as } \theta \rightarrow 0, \tag{82}$$

where U_j has the beta-binomial distribution Eq. (76).

To obtain the small θ approximation, we start with some properties of the beta and related functions (Abramowitz *et al.*, 1972). The beta function can be written in terms of gamma functions as

$$B(z_1, z_2) = \frac{\Gamma(z_1)\Gamma(z_2)}{\Gamma(z_1 + z_2)}. \quad (83)$$

For ε small and $n=1, 2, \dots$,

$$\Gamma(\varepsilon) = \frac{1}{\varepsilon} - \gamma + O(\varepsilon), \quad \Gamma(n + \varepsilon) = (1 + \varepsilon\psi(n))\Gamma(n) + O(\varepsilon^2), \quad (84)$$

where γ is Euler's constant and $\psi(z) = d\log\Gamma(z)/dz = \Gamma'(z)/\Gamma(z)$ is called the digamma function. It satisfies

$$\psi(1) = -\gamma, \quad \psi(n) = -\gamma + \sum_{i=1}^{n-1} \frac{1}{i}, \quad n = 1, 2, \dots \quad (85)$$

Armed with these properties, we have from Eq. (76)

$$\begin{aligned} \text{Prob}(U_j = 0) &= \binom{n_{\text{sample}}}{0} \frac{B(2(1-\alpha)\theta, n_{\text{sample}} + 2\alpha\theta)}{B(2(1-\alpha)\theta, 2\alpha\theta)} \\ &= \frac{\Gamma(n_{\text{sample}} + 2\alpha\theta)}{\Gamma(n_{\text{sample}} + 2\theta)} \cdot \frac{\Gamma(2\theta)}{\Gamma(2\alpha\theta)} \\ &= \frac{1 + 2\alpha\theta\psi(n_{\text{sample}})}{1 + 2\theta\psi(n_{\text{sample}})} \cdot \frac{1/(2\theta) - \gamma}{1/(2\alpha\theta) - \gamma} + O(\theta^2) \\ &= \alpha[1 - 2(1-\alpha)\theta\psi(n_{\text{sample}}) - 2(1-\alpha)\theta\gamma] + O(\theta^2) \\ &= \alpha - 2\alpha(1-\alpha)\theta \sum_{i=1}^{n_{\text{sample}}-1} \frac{1}{i} + O(\theta^2). \end{aligned} \quad (86)$$

Similarly,

$$\text{Prob}(U_j = n_{\text{sample}}) = 1 - \alpha - 2\alpha(1-\alpha)\theta \sum_{i=1}^{n_{\text{sample}}-1} \frac{1}{i} + O(\theta^2), \quad (87)$$

and Eq. (82) follows.

Multiple Alleles

We now consider extending the number of alleles from two to any number K . For instance, at any genomic site, the possible nucleotides are $\{A, C, G, T\}$, giving $K=4$ possible alleles.

In general we will label the alleles $A_1, \dots, A_K$, and consider a model with a fixed population size of M haploid or $M=2N$ diploid individuals. Define the random variables $Y_a(\tau)$ to be the number individuals of type A_a in the population at birth at the discrete times $\tau=0, 1, 2, \dots$, with the constraint that $\sum_{a=1}^K Y_a(\tau) = M$. The transition matrix Eq. (38) of the 2-allele WF model generalises to a matrix of probabilities of transitioning from a set of allele frequencies $\mathbf{i} = (i_1, \dots, i_K)$ to a set of allele frequencies $\mathbf{j} = (j_1, \dots, j_K)$ given by the multinomial distribution

$$\begin{aligned} p_{\mathbf{j}} &= \text{Prob}(\mathbf{Y}(\tau+1) = \mathbf{j} | \mathbf{Y}(\tau) = \mathbf{i}) \\ &= \begin{cases} \frac{M!}{\prod_{a=1}^K j_a!} \prod_{a=1}^K \psi_a(\mathbf{i})^{j_a} & \text{if } \sum_{a=1}^K i_a = \sum_{a=1}^K j_a = M, \\ 0 & \text{otherwise} \end{cases} \end{aligned} \quad (88)$$

where $\psi_a(\mathbf{i})$ is the probability of an individual inheriting allele type A_a given the previous generation's initial allele frequencies $\mathbf{i}$. This transition matrix defines a finite state Markov chain with a state space of dimension $\binom{M+K-1}{K-1}$, corresponding to the sites of a simplicial lattice in K dimensions. An example of the lattice is shown in Fig. 6 for the case $K=4$ and $M=30$.

Consider now the neutral WF model with K alleles. Suppose that u_{ab} , where $1 \leq a, b \leq K$, $u_{ab} \geq 0$ and $\sum_{b=1}^K u_{ab} = 1$, is the probability of an individual mutating from allele type A_a to type A_b in a single timestep. Generalising Eqs. (36) and (37) we have

$$\psi_a(\mathbf{i}) = \sum_{b=1}^K \frac{i_b}{M} u_{ba}. \quad (89)$$

The diffusion limit is obtained by defining random variables $X_a(t) = Y_a(\tau)/M$ equal to the relative proportion of type- A_a alleles within the population at continuous time $t = \tau/M$. The limit $M \rightarrow \infty$ and $u_{ab} \rightarrow 0$ for $a \neq b$ is taken in such a way that the $K \times K$

Fig. 6 Stationary distribution of allele frequencies for the multi-allele neutral WF model defined by Eqs. (88) and (89) for a haploid population of size $M=30$ and scaled rate matrix Q (see Eq. (90)) given by Eq. (95). The corners labelled A, C, G and T correspond to allele frequencies $\mathbf{i} = (N, 0, 0, 0)$, $(0, N, 0, 0)$, $(0, 0, N, 0)$ and $(0, 0, 0, N)$ respectively, and the volume of the sphere at each coordinate point is proportional to the probability mass function. Reproduced from Burden, C.J., Tang, Y., 2016. An approximate stationary solution for multi-allele neutral diffusion with low mutation rates. *Theoretical Population Biology* 112, 22–32.

instantaneous rate matrix Q , whose elements are defined by

$$q_{ab} = M(u_{ab} - \delta_{ab}), \quad (90)$$

remains finite. Here δ_{ab} is the Kronecker delta, equal to 1 if $a=b$ and 0 otherwise. Note that Eq. (90) is the generalisation of Eq. (55), and that Q is an instantaneous rate matrix (Isaev, 2004, Section 5.4) with the properties

$$q_{ab} \geq 0 \text{ for } a \neq b, \quad \sum_{b=1}^K q_{ab} = 0. \quad (91)$$

Using an argument similar to that illustrated by Fig. 3, the rate matrix Q can be identified as the whole-population substitution matrix relative to the continuum time t .

The diffusion limit gives the forward Kolmogorov equation

$$\frac{\partial f}{\partial t} = - \sum_{a=1}^{K-1} \frac{\partial}{\partial x_a} \sum_{b=1}^K x_b q_{ba} f + \frac{1}{2} \sum_{a,b=1}^{K-1} \frac{\partial^2}{\partial x_a \partial x_b} \{ (\delta_{ab} x_a - x_a x_b) f \}, \quad (92)$$

for the density function $f(x_1, \dots, x_{K-1}; t)$ of the vector of continuous random variables $X_1(t), \dots, X_{K-1}(t)$. The function f is defined over the simplex

$$\mathcal{S} = \left\{ (x_1, \dots, x_{K-1}) : x_1, \dots, x_{K-1} \geq 0, \sum_{a=1}^{K-1} x_a \leq 1 \right\}. \quad (93)$$

For notational convenience, we have defined $x_K = 1 - \sum_{a=1}^{K-1} x_a$ in Eq. (92), and also in Eq. (94) below. For details of the derivation of Eq. (92) see Lemma 4.1 of Etheridge (2011) or Eq. (5.125) of Ewens (2004).

Stationary Distribution of the Multi-Allele Neutral WF Model

The stationary distribution $f(x_1, \dots, x_{K-1})$ to the forward Kolmogorov equation is obtained by setting $\partial f / \partial t$ to zero on the left hand side of Eq. (92). The problem of finding an analytic stationary solution for an arbitrary rate matrix Q is as yet unsolved, though an exact analytic solution is known for a special case of parent-independent rate matrices in which the elements of the rate matrix take the form $q_{ab} = q_b$ (independent of a). In this case the solution is the multi-dimensional generalisation of the beta distribution, Eq. (61), namely the Dirichlet distribution (Wright, 1969; Tier and Keller, 1978; Griffiths, 1979):

$$f(x_1, \dots, x_{K-1}) = \frac{\Gamma(2 \sum_{a=1}^K q_a)}{\prod_{a=1}^K \Gamma(2q_a)} \prod_{a=1}^K x_a^{2q_a-1}. \quad (94)$$

Regrettably, there is no biological reason to consider parent-independent rate matrices, and in fact, most realistic models in phylogenetics are based on rate matrices such as the Hasegawa-Kishino-Yano (HKY) rate matrix (Hasegawa *et al.*, 1985), which are

not parent-independent. On the other hand, an accurate approximate solution is known in the biologically relevant limit of low scaled mutation rates, $q_{ab} \ll 1$ where $a \neq b$, for otherwise arbitrary rate matrices (Burden and Tang, 2016).

To understand the idea behind Burden and Tang's solution, consider for instance the numerical stationary solution to the discrete Wright-Fisher defined by Eqs. (88) to (90) shown in Fig. 6. For the purposes of illustration the solution has been simulated using an HKY matrix

$$Q = \begin{pmatrix} -0.11 & 0.03 & 0.06 & 0.02 \\ 0.02 & -0.09 & 0.03 & 0.04 \\ 0.04 & 0.03 & -0.09 & 0.02 \\ 0.02 & 0.06 & 0.03 & -0.11 \end{pmatrix} \quad (95)$$

and a small population $M=30$ in order to render the simulation numerically tractable. The mutation rates are unrealistically high by at least two orders of magnitude to enable the distribution to be visible over the entire simplex on the scale of the plot. Nevertheless, the distribution is dominated by the corners of the tetrahedron, indicating that the majority of genomic sites are not SNPs. Most of the remaining support of the distribution lies on the edges of the tetrahedron, which correspond to 2-allele SNPs. The interiors of the four faces, corresponding to 3-allele SNPs, and the interior volume of the tetrahedron, corresponding to 4-allele SNPs, account for only a small fraction of the total probability. This distribution is consistent with the observed occurrence of SNP multiplicities described at the beginning of the Introduction.

Exploiting this property of the low mutation rate limit, one can argue that the stationary distribution is concentrated close to the edges of the simplex S and can be represented accurately as a set of line densities defined along those edges. Suppose we label the corners of S by the allele prevalent within the population at that corner, so the corner A_a corresponds to the co-ordinate $(x_1, \dots, x_K) = e_a$, where e_a is the K -dimensional vector with 1 in the a th position and zeroes elsewhere, as illustrated in Fig. 6 for the 4-letter genomic alphabet. On the edge joining corner A_a to corner A_b a line density $f_{ab}(x)$ is defined for each pair of indices a and b , with the convention adopted that the argument x is the relative proportion of type- a alleles, and $1-x$ is the relative proportion of type- b alleles. The relative proportion of the remaining $K-2$ alleles along this edge is taken to be zero.

The line densities $f_{ab}(x)$ are solutions of an effective 2-allele model and satisfy a stationary forward Kolmogorov equation of the form of Eq. (60) with q_{12} and q_{21} replaced by q_{ab} and q_{ba} respectively. However, there is one major difference, namely that the constant on the right hand side can be a non-zero flux of probability Φ_{ab} flowing through the corners of the simplex S . Burden and Tang show that the presence of this flux modifies the approximate solution Eq. (65) to the form

$$f_{ab}(x) \approx C_{ab} \left(\frac{1}{x} + \frac{1}{1-x} \right) - \Phi_{ab} \left(\frac{1}{x} - \frac{1}{1-x} \right), \quad (96)$$

where the constants C_{ab} and Φ_{ab} are determined from rate matrix Q via the formulae

$$C_{ab} = \pi_a q_{ab} + \pi_b q_{ba}, \quad \Phi_{ab} = \pi_a q_{ab} - \pi_b q_{ba}. \quad (97)$$

Here $\pi^T = (\pi_1 \dots \pi_K)$ is the left eigenvector of Q satisfying

$$\pi_a \geq 0, \quad \sum_{a=1}^K \pi_a = 1, \quad \sum_{a=1}^K \pi_a q_{ab} = 0. \quad (98)$$

A sufficient condition for a unique π^T to exist is that $q_{ab} > 0$ for all $a \neq b$, which is expected to include any biologically realistic model. For computational reasons it is common in the phylogenetics literature to assume models in which rate matrices are reversible, that is, matrices satisfying the constraint $\pi_a q_{ab} = \pi_b q_{ba}$ (Lanave et al., 1984; Tavaré, 1986). We note that the introduction of non-zero values of the fluxes Φ_{ab} is equivalent to invoking non-reversible rate matrices.

The approximation Eq. (96) loses accuracy as the non-integrable singularities at $x=0$ and 1 are approached, that is, in the vicinity of the corners of S . However, one can show that for a population of size M , the value of the stationary distribution at the corners of the simplex corresponding to the discrete problem defined by Eqs. (88) and (89) is approximately

$$P(Y(\infty) = e_a) \approx \pi_a - \sum_{b \neq a} C_{ab} \log M. \quad (99)$$

The approximate stationary solution defined by Eqs. (96) and (99) reduces to the $K=2$ -allele approximate solution, Eqs. (65) and (66) on observing that, for a 2×2 rate matrix Q ,

$$(\pi_1, \pi_2) = \frac{1}{q_{12} + q_{21}} (q_{21}, q_{12}), \quad C_{12} = C_{21} = \frac{2q_{12}q_{21}}{q_{12} + q_{21}}, \quad \Phi_{12} = \Phi_{21} = 0. \quad (100)$$

Fig. 7 shows the numerically determined stationary solution for a population of size $M=30$ and the rate 4×4 matrix

$$Q^{\text{GRM}} = \begin{pmatrix} -5.375 & 3.125 & 2.125 & 0.1250 \\ 0.833 & -17.500 & 0.583 & 16.083 \\ 15.000 & 0.500 & -21.000 & 5.500 \\ 4.600 & 15.900 & 0.100 & -20.600 \end{pmatrix} \times 10^{-4}, \quad (101)$$

Fig. 7 Simulation of the neutral Wright-Fisher model with $K=4$ alleles and a population size $M=30$ and the rate matrix Q defined by Eq. (101). Blue crosses are the numerically determined stationary distribution along each edge of the simplex over which the site frequency distribution is defined. For any 2 alleles, A_a and A_b , the parameter x is the relative proportion of A_a alleles and $1-x$ is the relative proportion of A_b alleles. Superimposed in red are the theoretical line densities $f_{ab}(x)$, Eq. (96) plotted on a logarithmic scale. The red circles are the theoretical probabilities at the simplex corners, Eq. (99). The probabilities of the stationary distribution and the probabilities in Eq. (99) have been multiplied by a factor M for comparison with the continuum line densities.

plotted along each of the six edges of the simplex S , together with the approximate solution Eqs. (96) and (99). This matrix is taken from Eq. (53) of Burden and Tang (2017), and was chosen reproduce approximately the time-reversible matrix in Table 5 of Lanave *et al.* (1984) estimated from the rat-mouse phylogeny, with an arbitrary non-reversible part added.

Zeng (2010) has exploited the fact that stationary distributions of multi-allelic WF models are concentrated on the corners and edges of the simplex S to demonstrate that it is feasible to estimate all parameters of an evolutionary rate matrix Q from site-frequency data via numerical solution of the multi-allelic discrete WF model. Burden and Tang (2017) have extended the procedure to take advantage of the approximate analytic solution described above. Zeng's approach has the advantage the he is able to estimate selection parameters as well as mutation rates. On the other hand, Burden and Tang's approach has the advantages that the likelihood function takes a relatively simple analytic form entailing efficient numerical calculation for a given observed site-frequency data set, and that it provides a statistical test of the hypothesis, commonly assumed without biological justification, that the rate matrix is reversible.

Fig. 8 A coalescent tree of $n_{\text{sample}}=7$ individuals.

The Kingman Coalescent and the Watterson Estimator

The *coalescent* of a sample of individuals in a population is the ancestral lineage of the sample traced backwards in time to their most recent common ancestor. Use of the coalescent as a tool of analysis in population genetics was developed by a number of authors in the 1970s and early 1980s, though the definitive treatment of the subject is due to [Kingman \(1982, 2000\)](#). Here we give a brief description of the coalescent in the context of the haploid Wright-Fisher model, making use primarily of the property that each individual is the offspring of one randomly and independently chosen parent from the previous generation.

Define τ_C to be the number of generations counted backwards in time to the most recent common ancestor of two randomly chosen members of a population of size M . Clearly we have that $\text{Prob}(\tau_C = 1) = 1/M$ and $\text{Prob}(\tau_C \neq 1) = 1 - 1/M$. Given that generations are independent, the event " $\tau_C = \tau$ " corresponds to $\tau - 1$ generations for which the ancestral line traced backwards does not coalesce, followed by one generation for which the ancestral line does coalesce, thus

$$\text{Prob}(\tau_C = \tau) = \left(1 - \frac{1}{M}\right)^{\tau-1} \frac{1}{M}. \quad (102)$$

Now consider the continuum limit $M \rightarrow \infty$ defined with a continuous time $t = \tau/M$, $\delta t = 1/M$, which proved useful in calculations of the fixation time and for deriving the forward Kolmogorov Equation. Defining the continuous time to coalescence of a sample of size two as $T_2 = \tau_C/M$, [Eq. \(102\)](#) implies

$$\text{Prob}(t \leq T_2 < t + \delta t) = e^{-t} \delta t + O(\delta t^2). \quad (103)$$

Thus T_2 is an exponential random variable with rate 1. Moreover, we have that the probability that the next coalescent event backwards in time between two given individuals whose ancestry has not coalesced is

$$\text{Prob}(t \leq T_2 < t + \delta t | T_2 > t) = \delta t + O(\delta t^2). \quad (104)$$

Next we consider the coalescent of a sample of n_{sample} randomly chosen individuals, as shown in [Fig. 8](#). Define T_j to be the time interval between the coalescence event which reduces the ancestry to j individuals, and the coalescence event which reduces the ancestry to $j - 1$ individuals. At a point when the ancestry consists of j individuals there are $j(j-1)/2$ possibilities for the next pairwise coalescent event backwards in time. Thus from [Eq. \(104\)](#),

$$\text{Prob}(t \leq T_j < t + \delta t | T_j > t) = \frac{j(j-1)}{2} \delta t + O(\delta t^2), \quad (105)$$

which implies that the T_j are independent exponential random variables with respective rates $j(j-1)/2$, and that

$$E(T_j) = \frac{2}{j(j-1)}, \quad \text{Var}(T_j) = \frac{4}{j^2(j-1)^2}. \quad (106)$$

Set

$$W_{n_{\text{sample}}} = \sum_{j=2}^{n_{\text{sample}}} T_j, \quad (107)$$

to be the time back to the most recent common ancestor of the entire sample. The mean and variance of $W_{n_{\text{sample}}}$ are

$$\begin{aligned}
 E(W_{n_{\text{sample}}}) &= 2 \sum_{j=2}^{n_{\text{sample}}} \frac{1}{j(j-1)} \\
 &= 2 \sum_{j=2}^{n_{\text{sample}}} \left(\frac{1}{j-1} - \frac{1}{j} \right) \\
 &= 2 \left(1 - \frac{1}{n_{\text{sample}}} \right) \\
 &= 2 + O\left(n_{\text{sample}}^{-1}\right), \quad \text{as } n_{\text{sample}} \rightarrow \infty,
 \end{aligned} \tag{108}$$

and

$$\begin{aligned}
 \text{Var}(W_{n_{\text{sample}}}) &= 4 \sum_{j=2}^{n_{\text{sample}}} \left(\frac{1}{j-1} - \frac{1}{j} \right)^2 \\
 &= 8 \sum_{j=1}^{n_{\text{sample}}-1} \frac{1}{j^2} - 12 + \frac{8}{n_{\text{sample}}} + \frac{4}{n_{\text{sample}}^2} \\
 &= \frac{4\pi^2}{3} - 12 + O\left(n_{\text{sample}}^{-1}\right), \quad \text{as } n_{\text{sample}} \rightarrow \infty.
 \end{aligned} \tag{109}$$

Note that half of the contribution to $E(W_{n_{\text{sample}}})$ comes from the time taken for the coalescence of the earliest two ancestors, namely T_2 . To put it another way, the longest arms of the tree tend to be those for which there is a small number of individuals in the ancestry. Furthermore, as $n_{\text{sample}} \rightarrow \infty$ the expected coalescence time of the entire population is $2M(1 + O(1/M))$ generations, which is consistent with the time $\bar{\tau}^*(1)$ obtained in the section Expected time to Fixation for a mutation in a single individual to fix throughout the entire population.

Recall the Watterson estimator $\hat{\theta}_W$, Eq. (79), for the total mutation rate θ in neutral evolution, calculated in terms of the proportion S of segregating sites in the genomes of a sample of individuals. The total length of the branches of the coalescent tree can be used to show that $\hat{\theta}_W$ is an unbiased estimator of θ as follows. From Fig. 8, the total tree length is

$$L = \sum_{j=2}^{n_{\text{sample}}} jT_j. \tag{110}$$

If mutations are rare over the timescale of the figure and $\frac{1}{2}\theta$ is the average mutation rate per site (see Eq. (73)), then the proportion of segregating sites, conditional on the total length L of the tree, is a Poisson random variable with mean $\frac{1}{2}\theta L$. Then using the law of total expectation,

$$\begin{aligned}
 E(S) &= E(E(S|L)) \\
 &= \frac{1}{2}\theta E(L) \\
 &= \frac{1}{2}\theta \sum_{j=2}^{n_{\text{sample}}} jE(T_j) \\
 &= \theta \sum_{j=1}^{n_{\text{sample}}-1} \frac{1}{j}.
 \end{aligned} \tag{111}$$

It is then immediately obvious from Eq. (79) that $E(\hat{\theta}_W) = \theta$ and so $\hat{\theta}_W$ is an unbiased estimate of θ .

The Coalescent for Varying Populations

Slatkin and Hudson (1991) have generalised the coalescent for $n_{\text{sample}}=2$ individuals to the case of time-varying population sizes. Suppose we have a deterministically imposed varying population of size $M(\tau)$ where τ is the number of generations counted backwards in time from the present population, $M(0)=m_0$. Eq. (102) generalises to

$$\text{Prob}(\tau_C = \tau) = \prod_{\ell=1}^{\tau-1} \left(1 - \frac{1}{M(\ell)} \right) \frac{1}{M(\tau)}. \tag{112}$$

We define a continuous-time limit by setting

$$t = \frac{\tau}{m_0}, \quad \delta t = \frac{1}{m_0}, \quad T_2 = \frac{\tau_C}{m_0}, \quad v(t) = \frac{M(\tau)}{m_0}, \tag{113}$$

and taking the limit $m_0 \rightarrow \infty$. Rearranging Eq. (112) we have

$$\begin{aligned} \log(M(\tau)\text{Prob}(\tau_c = \tau)) &= \sum_{\ell=1}^{\tau-1} \log\left(1 - \frac{1}{M(\ell)}\right) \\ &= -\sum_{\ell=1}^{\tau-1} \left[\frac{1}{m_0 v(m_0 \ell)} + O\left(\frac{1}{m_0^2}\right) \right]. \end{aligned} \quad (114)$$

Thus

$$\log\left(\frac{v(t)}{\delta t} \text{Prob}(t \leq T_2 < t + \delta t)\right) = -\int_0^t \frac{du}{v(u)} + O(\delta t), \quad (115)$$

which rearranges to

$$\text{Prob}(t \leq T_2 < t + \delta t) = \frac{1}{v(t)} \exp\left(-\int_0^t \frac{du}{v(u)}\right) \delta t + O(\delta t^2). \quad (116)$$

The density function for the coalescent time T_2 is then

$$f_{T_2}(t) = \frac{1}{v(t)} \exp\left(-\int_0^t \frac{du}{v(u)}\right). \quad (117)$$

For the case of exponential population growth,

$$v(t) = e^{-\alpha t}, \quad (118)$$

one easily obtains

$$f_{T_2}(t) = e^{\alpha t} \exp\left(\frac{1 - e^{\alpha t}}{\alpha}\right), \quad 0 \leq t < \infty. \quad (119)$$

The mean time to coalescence is

$$E(T_2) = \frac{e^{1/\alpha}}{\alpha} E_1\left(\frac{1}{\alpha}\right), \quad (120)$$

where $E_1(z) = \int_z^\infty e^{-t}/t dt$ is the exponential integral (Abramowitz *et al.*, 1972, Eq. (5.5.1)). Slatkin and Hudson (1991) note that for $\alpha \gg 1$, the distribution is narrow and concentrated around a mean $E(T_2) \approx (\log \alpha - \gamma)e^{1/\alpha}/\alpha$ where $\gamma \approx 0.577$ is the Euler-Mascheroni constant.

Note that for a time-varying population the problem of determining the coalescent for $n_{\text{sample}} \geq 3$ individuals is nontrivial as the inter-coalescence times T_j illustrated in Fig. 8 are not mutually independent: There is no simple analog of Eq. (105) as restarting the clock at the last coalescence event requires knowing the population size at that event, which in turn depends on $T_{j+1} + \dots + T_{n_{\text{sample}}}$. For further analysis of this problem, including an explicit formula for the joint distribution of $T_2, \dots, T_{n_{\text{sample}}}$ see Griffiths and Tavaré (1994) and Chen and Chen (2013).

Alternatives to Wright-Fisher

So far we have concentrated only on the Wright-Fisher model. Below is a survey of some of the more important alternative models of population genetics.

The Moran Model

In common with the WF model, the *Moran model* (Moran, 1958) assumes a fixed population size and discrete time steps $\tau = 0, 1, 2, \dots$. The main difference, however, is that in the Moran model generations are allowed to overlap.

Consider the simplest form of the model, namely a haploid population of size M , each individual carrying one of two alleles, A_1 and A_2 , which are inherited without mutations. At each time step one randomly chosen member of the population reproduces, with the offspring carrying the same allele as the parent, and one randomly chosen individual, possibly the same individual, dies. With the convention that the number of individuals carrying allele A_1 at time step τ is $Y(\tau)$ the model defines a finite state Markov chain with transition probabilities

$$\begin{aligned} p_{ij} &= \text{Prob}(Y(\tau+1) = j | Y(\tau) = i) \\ &= \begin{cases} \frac{i(M-i)}{M^2} & \text{if } j = i \pm 1, \\ \frac{i^2 + (M-i)^2}{M^2} & \text{if } j = i, \\ 0 & \text{otherwise} \end{cases} \end{aligned} \quad (121)$$

for $i, j=0, \dots, M$. As for the WF model, it is easy to check that Eq. (3) holds, so that $Y(\tau)=0$ and $Y(\tau)=M$ are absorbing states of the Markov chain. Also Eqs. (8) and (9) hold, and so if $Y(0)=i$, either A_1 or A_2 must fix almost surely, with probabilities i/M and $1-i/M$ respectively.

The most straightforward way to include mutations dynamically in Eq. (121) is through the *decoupled Moran model*, which was introduced by Baake and Bialowons (2008) and Etheridge and Griffiths (2009) for the more general K -allele case. For 2 alleles the model is defined as

$$p_{ij} = \begin{cases} \frac{i(M-i)}{M^2} + u_{12} \frac{i}{M} & \text{if } j = i-1, \\ \frac{i^2 + (M-i)^2}{M^2} - u_{12} \frac{i}{M} - u_{21} \frac{M-i}{M} & \text{if } j = i, \\ \frac{i(M-i)}{M^2} + u_{21} \frac{M-i}{M} & \text{if } j = i+1, \\ 0 & \text{otherwise} \end{cases} \quad (122)$$

where u_{12} and u_{21} are mutation rates per unit of the time-step τ .

To obtain a sensible diffusion limit it is necessary to use a different scaling for the continuum time axis from that used for the WF model. It turns out that, if we define

$$t = \frac{2\tau}{M^2}, \quad \delta t = \frac{2}{M^2}, \quad X(t) = \frac{1}{M} Y(\tau), \quad q_{12} = \frac{1}{2} M u_{12}, \quad q_{21} = \frac{1}{2} M u_{21}. \quad (123)$$

then we again arrive at Eqs. (58) and (59), and hence recover identical forward and backward Kolmogorov equations as those for the WF model with mutations.

The Cannings Model

The WF and Moran models are particular cases of a class of models known collectively as the *Cannings model* (Cannings, 1974). Again consider a population of fixed size M and discrete generations $\tau=0, 1, 2, \dots$. Define a random vector

$$\mathbf{V}(\tau) = (V_1(\tau), \dots, V_M(\tau)), \quad (124)$$

equal to the (non-negative integer) number of offspring produced by the M individuals at time τ . The $V(\tau)$ are assumed to be i.i.d. for different τ , and to share their distribution with a generic random variable V satisfying firstly that

$$\sum_{\alpha=1}^M V_{\alpha} = M, \quad (125)$$

and secondly that

$$\text{Prob}(V_1 = v_1, \dots, V_M = v_M) = \text{Prob}(V_1 = v_{\pi(1)}, \dots, V_M = v_{\pi(M)}), \quad (126)$$

where $\pi(\cdot)$ is any permutation of the indices $1, \dots, M$. The second requirement is known as the exchangeability property, and the model is sometimes referred to as the Cannings exchangeable model. Note that Eqs. (125) and (126) imply that $E(V_{\alpha})=1$.

Suppose now that the population partitions into two alleles types, A_1 and A_2 , which are inherited without mutation. Let $Y(\tau)$ be the number of A_1 alleles and $M-Y(\tau)$ be the number of A_2 alleles present at time τ , so by appropriate labelling of the indices we can write

$$Y(\tau+1) = \sum_{\alpha=1}^{Y(\tau)} V_{\alpha}(\tau). \quad (127)$$

The 2-allele WF model without mutations is the particular case

$$\mathbf{V}^{\text{WF}} \sim \text{multinomial}\left(M; \frac{1}{M}, \dots, \frac{1}{M}\right), \quad (128)$$

and the Moran model is the particular case

$$\mathbf{V}^{\text{Moran}} \sim \text{uniform}\{(k_1, \dots, k_M) : (k_{\pi(1)}, \dots, k_{\pi(M)}) = (2, 0, 1, \dots, 1)\}. \quad (129)$$

Other specific cases are a trivial case in which each individual has exactly 1 offspring, for which neither allele ever fixes unless $Y(0)=0$ or M , and another trivial case in which one randomly chosen individual has all M offspring, in which the allele of the chosen individual fixes in 1 generation. In general, a Cannings model can be extended to include multiple alleles and may include neutral mutations, but not selection, as that would violate exchangeability.

The coalescent generalises easily to any Cannings model (Etheridge, 2011, Section 2.2). Recall that in deriving the coalescent for a WF model we defined τ_C to be the number of generations counted backwards in time to the most recent common ancestor of two randomly chosen individuals within the population. The probability that the two chosen individuals are siblings from the same parent α is $v_{\alpha}(v_{\alpha}-1)/(M(M-1))$, where v_{α} is the number of children produced by α . Defining c_M to be the probability that τ_C

is one generation, it follows that

$$\begin{aligned}
 c_M &= \text{Prob}(\tau_C = 1) \\
 &= \sum_{v_1, \dots, v_M} \text{Prob}(\tau_C = 1 | \mathbf{V}(-1) = (v_1, \dots, v_M)) \times \text{Prob}(\mathbf{V}(-1) = (v_1, \dots, v_M)) \\
 &= \sum_{v_1, \dots, v_M} \sum_{\alpha=1}^M \frac{v_\alpha(v_\alpha - 1)}{M(M-1)} \text{Prob}(\mathbf{V}(-1) = (v_1, \dots, v_M)) \\
 &= \frac{1}{M(M-1)} \sum_{\alpha=1}^M E[V_\alpha(V_\alpha - 1)] \\
 &= \frac{1}{M-1} E[V_1(V_1 - 1)] \\
 &= \frac{1}{M-1} \text{Var}(V_1),
 \end{aligned} \tag{130}$$

where we have used the exchangeability property in the second last line and the fact that $E(V_1) = 1$ in the last line. Eq. (102) then generalises to

$$\text{Prob}(\tau_C = \tau) = (1 - c_M)^{\tau-1} c_M. \tag{131}$$

The transition to a continuum time limit depends on the scaling behaviour of $\text{Var}(V_1)$ as $M \rightarrow \infty$. For instance, Eq. (51) defines an appropriate time scale for WF, while Eq. (123) defines an appropriate time scale for the Moran model. Once an appropriate coalescence time scale is established, the results in the section The Kingman Coalescent and the Watterson Estimator will in general carry through with appropriate modifications.

Branching Models

Branching models have their origins in the unpublished work of Bienaymé dating from 1845 (see Heyde and Seneta, 1972), and the work of Watson and Galton (1875) on the fate of patrilineally inherited family surnames. The Bienaymé-Galton-Watson (BGW) branching model differs from Cannings models in that the total population size is not fixed, or even specified deterministically, but varies stochastically.

Consider a population of $M(\tau)$ haploid individuals which are assumed to reproduce in discrete, non-overlapping generations $\tau = 0, 1, 2, \dots$. The population is partitioned into K allele types such that the number of copies of type k within the population is $Y_k(\tau)$. Thus $M(\tau) = \sum_{k=1}^K Y_k(\tau)$. In the simplest version of the model described here the alleles are assumed to be neutral with respect to selection and no mutation between allele types occurs. The central tenet of the BGW model is an assumption that the (non-negative integer) number of offspring per individual in any generation is given by a set of i.i.d. random variables $V_\alpha^{(k)}$, $\alpha = 1, \dots, Y_k(\tau)$, whose common distribution is denoted by a generic non-negative integer valued random variable V with mean and variance

$$E(V) = \lambda, \quad \text{Var}(V) = \sigma^2, \tag{132}$$

and finite moments to all higher orders. Thus

$$Y_k(\tau + 1) = \sum_{\alpha=1}^{Y_k(\tau)} V_\alpha^{(k)}, \tag{133}$$

and if the $Y_k(0)$ are mutually independent, then $Y_k(\tau)$ are mutually independent at all subsequent times τ . The standard formula for the mean of the sum of a random number of i.i.d. random variables (Ewens and Grant, 2005, p90) gives $E(Y_k(\tau + 1)) = \lambda E(Y_k(\tau))$. Given initial conditions

$$Y_k(0) = i_k, \quad M(0) = m_0 = \sum_{k=0}^K i_k, \tag{134}$$

it follows that

$$E(Y_k(\tau)) = i_k \lambda^\tau, \quad E(M(\tau)) = m_0 \lambda^\tau. \tag{135}$$

Consider now the fate of any one allele, the number of copies of which we will denote generically as $Y(\tau)$. If the probability generating functions of V and $Y(\tau)$ are respectively

$$G_V(\xi) = E(\xi^V), \quad G_{Y(\tau)}(\xi) = E(\xi^{Y(\tau)}), \tag{136}$$

then the formula for the probability generating function for the sum of a random number of i.i.d. random variables (Johnson *et al.*, 1993, p344) gives

$$G_{Y(\tau+1)}(\xi) = G_{Y(\tau)}(G_V(\xi)). \tag{137}$$

Fig. 9 The stable fixed point of $\zeta = G_V(\zeta)$.

Suppose we start with an initial population of just one individual, in which case $Y(0)=1$ and $G_{Y(0)}(\xi)=\xi$. Applying the above iterative formula gives

$$\begin{aligned} G_{Y(1)}(\xi) &= G_{Y(0)}(G_V(\xi)) = G_V(\xi), \\ G_{Y(2)}(\xi) &= G_{Y(1)}(G_V(\xi)) = G_V(G_V(\xi)), \\ &\vdots \\ G_{Y(\tau)}(\xi) &= \underbrace{G_V(G_V(\dots G_V(\xi)\dots))}_{\tau \text{ times}} = G_V(G_{Y(\tau-1)}(\xi)). \end{aligned} \quad (138)$$

Also, since

$$G_{Y(\tau)}(\xi) = \sum_{y=0}^{\infty} \xi^y \text{Prob}(Y(\tau)=y) = \text{Prob}(Y(\tau)=0) + O(\xi), \quad (139)$$

the probability of extinction at or before generation τ is

$$\text{Prob}(Y(\tau)=0) = G_{Y(\tau)}(0). \quad (140)$$

Thus the probability of eventual extinction, $\zeta = \text{Prob}(Y(\infty)=0) = G_{Y(\infty)}(0)$, is, by Eq. (138), the stable fixed point of the iterative equation

$$\zeta = G_V(\zeta). \quad (141)$$

Noting that

$$G_V(1)=1, \quad G'_V(1)=\lambda, \quad \text{and } G''_V(1)=\sigma^2 + \lambda^2 - \lambda > 0, \quad (142)$$

since $\lambda^2 - \lambda = E(V(V-1)) \geq 0$ if V only takes values $0, 1, 2, \dots$, the graph of $G_V(\xi)$ passes through $(1, 1)$ with slope λ and is convex, as shown in Fig. 9. It follows that

$$\zeta \begin{cases} < 1 & \text{if } \lambda > 1, \\ = 1 & \text{if } \lambda \leq 1. \end{cases} \quad (143)$$

Moreover, since lineages are independent, if the initial abundance of an allele is $Y(0)=i$, then the probability of eventual extinction is

$$\text{Prob}(Y(\infty)=0|Y(0)=i) = \begin{cases} \zeta^i & \text{if } \lambda > 1, \\ 1 & \text{if } \lambda \leq 1. \end{cases} \quad (144)$$

The upshot of this is that each allele will almost surely eventually become extinct in the case of sub-critical growth, $\lambda < 1$, or critical growth, $\lambda = 1$, and that there is a finite probability $1 - \zeta^i$ that an allele will never become extinct in the case of supercritical growth, $\lambda > 1$. Furthermore, in the presence of 2 alleles with initial abundances i_1 and i_2 and supercritical growth, there is a probability $(1 - \zeta^{i_1})(1 - \zeta^{i_2})$ that the population will persist indefinitely with neither allele ever fixing throughout the population.

The Continuum Bienaymé-Galton-Watson Branching Model

The diffusion approximation of a BGW branching process via a forward Kolmogorov diffusion equation has been analysed in detail by Feller (1951a) and is summarised in the texts by Bailey (1964) and Cox and Miller (1978). For an analysis in the context of genetic drift, see Burden and Simon (2016).

For each allele type A_k the continuum limit is obtained by defining

$$t = \frac{\tau}{m_0}, \quad \delta t = \frac{1}{m_0}, \quad X_k(t) = \frac{Y_k(\tau)}{m_0}, \quad x_{k0} = \frac{i_k}{m_0}, \quad (145)$$

where m_0 and i_k are the initial conditions specified in Eq. (134). The simultaneous limits $m_0 \rightarrow \infty$, $\lambda \rightarrow 1$ are then taken in such a way that

$$\alpha = m_0 \log \lambda, \quad (146)$$

and σ^2 remain fixed. Setting $\delta X_k(t) = (Y_k(\tau + 1) - Y_k(\tau))/m_0$, one obtains

$$\begin{aligned} E(\delta X_k(t) | X_k(t) = x) &= \frac{1}{m_0} (\lambda - 1) x m_0 \\ &= \alpha x \delta t + o(\delta t), \end{aligned} \quad (147)$$

and

$$\begin{aligned} E(\delta X_k(t)^2 | X_k(t) = x) &= \text{Var}(\delta X_k(t) | X_k(t) = x) + E(\delta X_k(t) | X_k(t) = x)^2 \\ &= \frac{1}{m_0^2} \sigma^2 x m_0 + O\left(\frac{1}{m_0^2}\right) \\ &= \sigma^2 x \delta t + o(\delta t). \end{aligned} \quad (148)$$

Comparing with the general form Eqs. (53) and (54) yields the forward Kolmogorov equation for the density function $f_{Xk}(x, t)$,

$$\frac{\partial f_{Xk}}{\partial t} = -\alpha \frac{\partial}{\partial x} (x f_{Xk}) + \frac{1}{2} \sigma^2 \frac{\partial^2}{\partial x^2} (x f_{Xk}). \quad (149)$$

The process defined by this forward Kolmogorov equation is often referred to as a *Feller diffusion*.

The solution obtained by Feller (1951a,b) corresponding to the initial condition $f_{Xk}(x, 0) = \delta(x - x_{k0})$ is

$$\begin{aligned} f_{Xk}(x, t) &= \delta(x) p_0(t) \\ &\quad + \tilde{\kappa}(t) \left(\frac{x_{k0} e^{-\alpha t}}{x} \right)^{\frac{1}{2}} \exp\{-\tilde{\kappa}(t)(x_{k0} + x e^{-\alpha t})\} I_1\left(2\tilde{\kappa}(t)(x_{k0} x e^{-\alpha t})^{\frac{1}{2}}\right) \end{aligned} \quad (150)$$

where $\delta(x)$ is the Dirac delta function defined in Appendix A, $I_1(\cdot)$ is the modified Bessel function of order 1,

$$\tilde{\kappa}(\tau) = \begin{cases} \frac{2\alpha}{\sigma^2(1 - e^{-\alpha t})} & \text{if } \alpha \neq 0 \\ \frac{2}{\sigma^2 t} & \text{if } \alpha = 0, \end{cases} \quad (151)$$

and

$$p_0(t) = e^{-\tilde{\kappa} x_{k0}}. \quad (152)$$

An outline of Feller's derivation of this solution using the Laplace transform of $f_{Xk}(x, t)$ is given on pages 235 and 250 of Cox and Miller (1978).

The delta-function term represents a point mass at zero indicating the finite probability $p_0(t)$ that the allele becomes extinct at or before time t . The probability of eventual extinction is

$$\lim_{t \rightarrow \infty} p_0(t) = \begin{cases} 1 & \text{if } \alpha \leq 0, \\ e^{-2\alpha x_{k0}/\sigma^2} & \text{if } \alpha > 0. \end{cases} \quad (153)$$

It can be checked that this is consistent with the corresponding probability of extinction for the discrete case as follows. From Eqs. (141) and (142),

$$\zeta = 1 + \lambda(\zeta - 1) + \frac{1}{2}(\sigma^2 + \lambda^2 - \lambda)(\zeta - 1)^2 + O((\zeta - 1)^3). \quad (154)$$

Solving for the stable root shown in Fig. 9, and noting that ζ is close to 1 for λ close to 1, we have either $\zeta = 1$ if $\lambda \leq 1$, or

$$\begin{aligned} \zeta &= 1 + \frac{2(1 - \lambda)}{\sigma^2} + O((\lambda - 1)^2) \\ &= 1 - \frac{2 \log \lambda}{\sigma^2} + O((\log \lambda)^2) \\ &= 1 - \frac{2\alpha}{m_0 \sigma^2} + O\left(\frac{1}{m_0^2}\right), \end{aligned} \quad (155)$$

if $\lambda > 1$. In the continuum limit, and noting that $i_k = m_0 x_{k0}$, Eq. (144) gives the probability of extinction for the $\lambda > 1$ case as

$$\lim_{m_0 \rightarrow \infty} \left(1 - \frac{2\alpha}{m_0 \sigma^2} \right)^{m_0 x_{k0}} = e^{-2\alpha x_{k0} / \sigma^2}, \quad (156)$$

agreeing with the $\alpha > 0$ case of Eq. (153). The $\alpha \leq 0$ case clearly corresponds to the $\lambda \leq 1$ stable solution.

For the critical value $\alpha = 0$ and $K = 2$ alleles, Burden and Simon, (2016) have shown that the diffusion limit of the BGW model has similar, but not identical, distributions of fixation times to the neutral WF and Cannings models without mutations. More specifically, they demonstrate that, given an initial population in which a fraction x_0 are of allele-type A_1 and a fraction $1 - x_0$ are of allele-type A_2 , the probability that A_1 fixes is x_0 , and the probability that A_2 fixes is $1 - x_0$, in agreement with Eqs. (8) and (9) for the WF model. Furthermore, if $T^*(x_0)$ is defined to be the time for A_1 to fix, conditional on A_1 fixing from an initial population x_0 , then

$$E(T^*(x_0)) = -\frac{2(1-x_0)}{x_0 \sigma^2} \log(1-x_0). \quad (157)$$

When $\sigma^2 = 1$ this result agrees with the fixation time for the WF model, Eq. (34). On the other hand, it can be shown that the variance of $T^*(x_0)$ differs from that of the Wright-Fisher model. Results for fixation probabilities can be extended to the case of supercritical growth, $\alpha > 0$, with complications due to the fact that there is a finite probability that neither allele ever fixes.

Closing Remarks

The intention behind this article is to provide a solid mathematical background to many of the models underpinning current research in population genetics. No survey of this length could possibly cover all aspects of mathematical population genetics.

Some of the basic topics we have not covered include infinitely-many alleles models (Kimura and Crow, 1964), tests for neutrality versus selection such as Tajima's D statistic (Tajima, 1989), and interactions between multiple loci, which is also known as epistasis. Also not covered are non-random mating, recombination, and selective sweeps, that is, loss of genetic variation in the genomic vicinity of a beneficial mutation. The basic form of the WF and more general exchangeable models can be extended to study spatially structured populations and gene flow, including the transfer of alleles from one population to another due to migration. From the mathematical point of view, the diffusion limit of any model accessible to the forward Kolmogorov equation can equally be analysed in terms of stochastic differential equations.

The coalescent has had a major influence on the population genetics literature as improvements in genotyping technologies and the development of several software packages for simulating genealogies have become available, and perhaps deserves an extensive review in its own right.

From the point of view of population sizes, loss of genetic diversity through population bottlenecks and the founder effect are also of interest. Finally, the Bienaymé-Galton-Watson branching model can be adapted in a number of ways. Two examples are the stabilization of population size by introducing logistic growth (Lambert et al., 2005), and the introduction of multiple alleles via multitype branching processes (Mode, 1971).

Appendix A Derivation of the Forward Kolmogorov Equation

In order to facilitate the derivation of the forward Komogorov equation we first make a short digression to introduce a mathematical abstraction known as the Dirac delta function. The Dirac delta function (or just 'delta function' for short) is an example of a construct known to pure mathematicians as a generalised function. It was introduced by the physicist Paul Dirac (1930) as a convenient notation for studying quantum mechanics and was subsequently formalised rigorously by the mathematician Laurent Schwartz. However, to have a practical working understanding of the delta function it is not necessary to delve into the arcane pure mathematics of generalised functions. Here we take a simple but adequate heuristic approach.

The Dirac delta function, $\delta(x)$ is equal to zero everywhere on the real number line except at $x=0$, where it is envisaged as an infinite spike, the area beneath which is 1. Thus

$$\delta(x) = \begin{cases} \infty & \text{if } x = 0, \\ 0 & \text{if } x \neq 0, \end{cases} \quad (A.1)$$

and

$$\int_{-\varepsilon}^{\varepsilon} \delta(x) dx = 1, \quad (A.2)$$

for any $\varepsilon > 0$. The delta function can be represented as a limit of the normal distribution density functions centred about zero as the variance tends to 0 (see Fig. 10). An important property of the delta function is that, for any function $f(x)$ which is continuous at $x=a$,

$$\int_{-\infty}^{\infty} f(x) \delta(x-a) dx = f(a). \quad (A.3)$$

Fig. 10 Representation of the Dirac delta function as the limit of a normal distribution centred about zero as its variance σ^2 tends to zero.

Fig. 11 Derivation of the forward Kolmogorov equation: decomposing $f(x, p, t + \delta t)dx$ into a sum over paths through intermediate events $u \leq X(t) < u + du$ at time t .

By formally integrating by parts we also obtain meaning for derivatives of the delta function, namely

$$\int_{-\infty}^{\infty} f(x) \delta'(x-a) dx = -f'(a), \quad \int_{-\infty}^{\infty} f(x) \delta''(x-a) dx = f''(a). \quad (\text{A.4})$$

We will derive the forward Kolmogorov equation for a generic population genetics model based on a discrete time finite state Markov chain. As previously, consider a genomic site at which two alleles A_1 and A_2 are possible in a population of fixed size M , and let the random variable $Y(\tau)$ be the number of A_1 alleles present at timestep $\tau=0,1,2,\dots$ labelling non-overlapping generations. The range of $Y(\tau)$ is $\Omega_{Y(\tau)} = \{0, \dots, M\}$. Assume also that we are given a time-independent Markov transition matrix

$$p_{ij} = \text{Prob}(Y(\tau+1) = j | Y(\tau) = i), \quad i, j = 0, \dots, M. \quad (\text{A.5})$$

With the intention of taking the limit $M \rightarrow \infty$, make the substitutions:

$$t = \frac{\tau}{M}, \quad \delta t = \frac{1}{M}, \quad X(t) = \frac{1}{M} Y(\tau),$$

$$\delta X(t) = X(t + \delta t) - X(t) = \frac{1}{M} [Y(\tau+1) - Y(\tau)]. \quad (\text{A.6})$$

After taking the limit $M \rightarrow \infty$, t becomes a continuous time variable over the interval $[0, \infty)$ and the fraction $X(t)$ of the population with allele A_1 becomes a continuous random variable with range $\Omega_X = [0, 1]$. Now define the probability density $f(x; p, t)$ corresponding to $X(t)$, conditional on the initial condition $X(0) = p$, that is,

$$f(x; p, t) dx = \text{Prob}(x \leq X(t) < x + dx | X(0) = p), \quad 0 \leq x, p \leq 1, \quad t > 0. \quad (\text{A.7})$$

Our aim is to find a partial differential equation governing the evolution of $f(x; p, t)$.

The derivation of the forward Kolmogorov equation begins with decomposing $\text{Prob}(x \leq X(t + \delta t) < x + dx | X(0) = p)$ into a sum over intermediate events $u \leq X(t) < u + du$, which we write formally as

$$\begin{aligned} & \text{Prob}(x \leq X(t + \delta t) < x + dx | X(0) = p) \\ &= \sum_{u \in [0,1]} \text{Prob}(x \leq X(t + \delta t) < x + dx | u \leq X(t) < u + du) \\ & \quad \times \text{Prob}(u \leq X(t) < u + du | X(0) = p). \end{aligned} \quad (\text{A.8})$$

A path through one such intermediate state is shown in Fig. 11. At this point one should think of du and dx as being infinitesimal, and δt as being finite but small, in which case we can use Eq. (A.7) to rewrite the formal sum over u as

$$f(x; p, t + \delta t) = \int_0^1 du f(x; u, \delta t) f(u; p, t). \quad (\text{A.9})$$

In order to make sense of the last equation we introduce one more assumption, namely that the moments of the random variable $\delta X(t)$ defined by Eq. (A.6) are of the form

$$\begin{aligned} E[\delta X(t) | X(t) = u] &= a(u)\delta t + o(\delta t) \\ E[(\delta X(t))^2 | X(t) = u] &= b(u)\delta t + o(\delta t) \\ E[(\delta X(t))^k | X(t) = u] &= o(\delta t), \quad k = 3, 4, \dots \end{aligned} \quad (\text{A.10})$$

as $\delta t \rightarrow 0$ for finite, well behaved functions $a(u)$ and $b(u)$ defined for $0 \leq u \leq 1$. This assumption essentially means that the density function $f(x; u, \delta t)$ is a narrow distribution centred about a mean approximately equal to $u + a(u)\delta t$ with variance approximately equal to $b(u)\delta t$ when δt is small. In other words, the point x in Fig. 11 is unlikely to stray further than a distance of $O(\sqrt{\delta t})$ from the point u . We claim we can therefore represent $f(x; u, \delta t)$ in terms of the Dirac delta function as

$$f(x; u, \delta t) = \delta(x - u) - a(u)\delta'(x - u)\delta t + \frac{1}{2}b(u)\delta''(x - u)\delta t + o(\delta t). \quad (\text{A.11})$$

One can check using the properties of the delta function that this is consistent with Eq. (A.10). For instance,

$$\begin{aligned} E[\delta X(t) | X(t) = u] &= E[X(t + \delta t) - X(t) | X(t) = u] \\ &= \int_0^1 (x - u) f(x; u, \delta t) dx \\ &= \int_0^1 (x - u) [\delta(x - u) - a(u)\delta'(x - u)\delta t + \frac{1}{2}b(u)\delta''(x - u)\delta t] dx + o(\delta t) \\ &= 0 + \int_0^1 \left[\frac{\partial}{\partial x} (x - u) \right] a(u) \delta(x - u) \delta t dx \\ & \quad + \frac{1}{2} \int_0^1 \left[\frac{\partial^2}{\partial x^2} (x - u) \right] b(u) \delta(x - u) \delta t dx + o(\delta t) \\ &= 0 + \int_0^1 a(u) \delta(x - u) \delta t dx + 0 + o(\delta t) \\ &= a(u)\delta t + o(\delta t). \end{aligned} \quad (\text{A.12})$$

Similarly one can confirm the remaining two expectation values.

Returning to Eq. (A.9) and expanding the left hand side to first order in δt , we have

$$\begin{aligned} & f(x; p, t) + \frac{\partial f(x; p, t)}{\partial t} \delta t \\ &= \int_0^1 f(u; p, t) [\delta(x - u) - a(u)\delta'(x - u)\delta t + \frac{1}{2}b(u)\delta''(x - u)\delta t] du + o(\delta t) \\ &= f(x; p, t) - \int_0^1 \frac{\partial}{\partial u} [f(u; p, t) a(u)] \delta(x - u) \delta t du \\ & \quad + \frac{1}{2} \int_0^1 \frac{\partial^2}{\partial u^2} [f(u; p, t) b(u)] \delta(x - u) \delta t du + o(\delta t) \\ &= f(x; p, t) + \left(-\frac{\partial}{\partial x} [f(x; p, t) a(x)] + \frac{1}{2} \frac{\partial^2}{\partial x^2} [f(x; p, t) b(x)] \right) \delta t + o(\delta t). \end{aligned} \quad (\text{A.13})$$

Equating the coefficient of δt on both sides finally gives the forward Kolmogorov equation

$$\frac{\partial f(x; p, t)}{\partial t} = -\frac{\partial}{\partial x}[a(x)f(x; p, t)] + \frac{1}{2}\frac{\partial^2}{\partial x^2}[b(x)f(x; p, t)]. \quad (\text{A.14})$$

For any specific population genetics model, the functions $a(x)$ and $b(x)$ are determined from the Markov transition matrix p_{ij} .

One can perform a similar calculation by partitioning the path from $X(0)=p$ to $X(t+\delta t)=x$ into an interval 0 to δt and an interval from δt to $t+\delta t$ to obtain the *backward Kolmogorov equation* (Ewens, 2004, p138)

$$\frac{\partial f(x; p, t)}{\partial t} = a(p)\frac{\partial}{\partial p}f(x; p, t) + \frac{1}{2}b(p)\frac{\partial^2}{\partial p^2}f(x; p, t). \quad (\text{A.15})$$

The backward equation yields the same solution as the forward equation, the difference being that in the forward equation $f(x; p, t)$ is treated as a function with independent variables x and t , and p treated as a parameter, whereas in the backward equation $f(x; p, t)$ is treated as a function with independent variables p and t , and x treated as a parameter.

Biographical Sketch

Conrad Burden is an associate professor in the Mathematical Sciences Institute at the Australian National University lecturing in bioinformatics and biological modelling. His research interests include mathematical population genetics, alignment-free sequence comparison, the analysis of high-throughput sequencing data, and the physico-chemical modelling of microarrays. Before making the move into bioinformatics in 2003 he spent 20 years as a theoretical physicist followed by a short period working in the IT industry. He graduated from the University of Queensland with first class honours in Applied Mathematics in 1979 and The Australian National University with a PhD in Theoretical Physics in 1983. Between 1983 and 1988 he held postdoctoral fellowships in theoretical physics at the Weizmann Institute of Science, Glasgow University, The Australian National University and Flinders University. Between 1988 and 1999 he held a research position in the Department of Theoretical Physics, Australian National University, working mainly in quantum field theory and subatomic particle physics. Between 1999 and 2002 he was a programmer/developer in the IT industry. He is a Fellow of the Australian Institute of Physics.

Computational Systems Biology

Introduction

Rapid advancements in novel and high throughput technologies to observe and record different biological players and their interactions in multi-dimensions have opened interesting “Big Data” challenges. Using novel computational methods to use all this data to convert them into actionable insights is crucial in the biomedical domain. This is even more relevant in systems biology based approaches where the motivation is to use computational techniques to connect and reconcile data from different spatiotemporal scales to gain a systems level understanding of biological systems.

Extensive literature is available in the community highlighting the variety of tools, algorithms and databases available for different aspects of analysis in systems biology (Ghosh *et al.*, 2011) – from Data and Knowledge management, deep curation, *in silico* simulation and model analysis, to physiological modeling, molecular interaction modeling (Kröger and Bry, 2003; Brazma *et al.*, 2006). Successful application of these methodologies in modeling cell cycle dynamics, such as a computational model that explained the effects of over 120 knockout mutations on cell cycle dynamics in yeast (Tyson *et al.*, 2001; Novak and Tyson, 1993), have been demonstrated. Significant progress has also been made in the analysis of signaling pathways – for example, in understanding the dynamics of mitogen-activated protein kinase (MAPK) signaling (Chen *et al.*, 2004; Aoki *et al.*, 2011) – and in cancer drug discovery applications, in which a reagent that was developed using model-based computational analysis is now in clinical trials (Schoeberl *et al.*, 2009, 2010).

Current tools and techniques in computational systems biology has demonstrated their usage in various application areas, as illustrated schematically in Fig. 1. At the same time, the shift in paradigm both in experimental techniques which generate vast quantities of data, and in powerful data analytics, modeling and visualization methodologies, entail the empowerment of computational systems biology models and methodologies which leverage developments in machine learning, big data management and analysis, large scale modeling and simulations, to name a few. This topic article endeavors to provide some key areas of modeling and methodologies – highlighting new directions and developments, to enable computational systems biology to address the new challenges in biology and medicine.

The rest of the paper provides a brief overview of some of the key model and methodologies – including, Pathway Curation, Network analysis, Modeling and Simulation and Data Analytics. We conclude with a perspective on the promises and perils for application of novel models and methodologies in deeper understanding of basic biology as well as drug discovery and healthcare.

Pathway Curation

Biological systems can be thought of as composition of different biological players whose concerted actions lead to the biological function. Advances in high throughput technologies for recording these interactions have led to increased data which

Fig. 1 Models and methodologies in computational systems biology. Taken from Hird, N., Ghosh, S., Kitano, H., 2016. Digital health revolution: Perfect storm or perfect opportunity for pharmaceutical R&D? Drug Discovery Today 21 (6), 900–911. Available at: <http://doi.org/10.1016/j.drudis.2016.01.010>.

has led to increased understanding about these molecules and their associated interactions. With this one can now more objectively reason about how these biological players work in unison at the systems level to perform various biological functions. Systematically recording and understanding these interactions is important and for this we construct and use Pathway maps. Pathway maps can be thought of as a formal representation of the collection of interactions among various biological players. They represent important insights pertaining to the flow of information within a biological system. They could either encode chemical reactions which are involved in the production or breakdown of different metabolites (metabolic pathways), or regulatory interaction between genes and proteins (gene regulatory networks) or record interactions that occur in response to external/internal stimuli (signaling pathways). Studying, analyzing and simulating these pathways can lead to crucial insights leading to designing effective cures for diseases (Kitano, 2002). One of the important undertakings in systems biology is creating formal (and machine readable) representations of these pathways and constitutes the task of Pathway curation (Kitano *et al.*, 2005). Pathways are usually encoded using standards such as SBML (Hucka *et al.*, 2003) and BioPAX (Demir *et al.*, 2010). Numerous pathway databases such as KEGG (Kanehisa and Goto, 2000) and Reactome (Joshi-Tope *et al.*, 2005) store pathway interactions. Attempts to construct detailed process level maps (such as the mTOR pathway map (Caron *et al.*, 2010) and TLR pathway map (Oda and Kitano, 2006)) and disease level pathway maps (such as Alzheimer's (Mizuno *et al.*, 2012) and Parkinson disease maps (Fujita *et al.*, 2014)) have been undertaken.

Typically, pathways are constructed and curated by expert pathway curators who manually read relevant scientific literature in detail, comprehend and select the relevant information about molecular interactions relevant in context and represent it as a pathway diagram. This process is facilitated by several graphical tools such as CellDesigner (Funahashi *et al.*, 2008).

The primary issues with manual approach to pathway curation is time consuming, importantly that the scale at which basic research is progressing, it is often hard to keep pace. Many times, the interpretation of the details is left to the judgment of the curator, hence leading to considerable inter-curator variability. Next, as new research finding are reported, these pathway maps need to be updated or augmented and doing this manually is almost impossible. Developing (semi) automated pathway curation methods using text mining and natural language processing (NLP) for has been an active field of research (Ananiadou *et al.*, 2010; Chowdhury and Sarkar, 2015; Cohen, 2015; Valenzuela-Escarcega *et al.*, 2015;) and is among important goals of large funded research efforts such as the recent DARPA's Big Mechanism Project (Cohen, 2015).

The task of automated pathway curation is essentially that of event extraction where given a text, the task of the automated system will be to first identify different biologically relevant players (using Named entity recognition), identifying the events (or reactions) and mapping the identified biological players to the corresponding reactions. There have been numerous tools such as TEES (Bjorne and Salakoski, 2011), Reach framework (Valenzuela-Escarcega *et al.*, 2015) and more recently the INDRA (Gyori *et al.*, 2017) which specifically tackle this problem. All these methods try to solve the problem of assembling individual reactions types and evaluating their performance. While this is useful, there has been limited acceptance of these techniques in the mainstream curation community. This is primarily because current extraction methods look at the atomic task of extracting at reaction level from text, while ignoring the aspect of threading these pieces together to reconstruct a holistic picture of the pathway (network). In fact, when a human curator is building a pathway map, he is thinking in terms of a network as the ultimate objective which is not well captured by the current NLP techniques.

There have been recent efforts to study and bridge this gap recently (Spranger *et al.*, 2016, 2015). These studies highlight some crucial aspects of improvement for current event extraction systems such as species normalization (improvements needed in unambiguous disambiguation of biological players), Complex identification, looking at a holistic view of the pathway outcome rather than focus only on reaction inference and finally for NLP systems to understand the level of abstraction at which a human interprets the publication and represents it on the pathway map.

Network Based Approaches

Once a pathway map (essentially a network) is obtained after curation, multiple analysis tasks can be carried out. The most straight forward is to purely consider the pathway as a network and performing static analysis on it.

Controllability/Network Motif Analysis

Controllability analysis focuses on analyzing a complex pathway network with the goal of providing insights about the key genes/proteins (called drivers) required to control the network, whose perturbation has a profound impact on the state of the network (Liu *et al.*, 2011). Network controllability has been successfully used in the context of large biological network to characterize how biological networks have special properties which confer then unique capabilities (Müller and Schuppert, 2011; Kawakami *et al.*, 2016). This can be useful for designing therapeutic interventions where identifying the drivers of a network and characterizing their relative importance in changing healthy to disease state is important for targeting them.

Since the pathway is essentially a network/graph, analyzing the structure of the graph can reveal unique substructures within the network that are expressed in majority and confer specific properties to the network. These substructures are often called network motifs and they are believed to serve as building blocks of the network. These network motifs and the impact they have on

the dynamic features and biological functions of the overall network is well studied. In fact, it is believed that these motifs play a crucial part in the regulation and robustness of the network (Shen-Orr *et al.*, 2002; Novák and Tyson, 2008).

Network Inference

While pathway curation concerns with organizing the current knowledge about pathways one the other interesting facet is to discover new previously unknown links in the pathway network. Again, thanks to the high through put technologies, we can measure thousands of biomolecules concurrently over time. The data that is produced from these experiments can be used to discover novel pathway links or study how pathways and their links get affected in diseases/healthy states. The field of network inference deals with inferring these causal relationships between biological players from experimental data. The process is challenging as the network of molecular interactions are complex have numerous control and regulatory mechanisms governing the interactions and the experimental measurements are currently sparse and noisy.

There has been a lot of effort in developing and using efficient algorithms to infer these networks (Hase *et al.*, 2013; Sachs *et al.*, 2009, 2005). Considerable effort needs to also be put into producing accurate networks even with noisy observation data and will continue to be a major challenge in this field.

Modeling and Simulation

Pathway maps such as those discussed the pathway curation section provide a static picture of the events transpiring in a cell, however the dynamics of their interaction in time and space is what confers cellular function and behavior. For this, modeling pathway systems using mathematical formulations and consequently analyzing these models using techniques such as simulations is crucial.

Usually, for modeling studies, one starts from curated pathway maps which statically encode our understand of the mechanisms. A part of the map which is relevant to the current study is isolated after which suitable modeling formalism is chosen to mathematically encode interactions or hypotheses. These mathematical formalisms have kinetic parameters which need to be tuned so that these models faithfully replicate the observed dynamics and forms a large part of the model calibration and validation efforts. Once a model is calibrated, it faithfully captures the dynamics of the underlying system and can now be used for further analysis. These models once calibrated, can be used to predict behavior of the system under perturbations which is crucial to assess robustness of the system. Additionally, they can potentially assist in designing better experiments whereby one can evaluate potential hypotheses on the models first (which have considerably less cost) before validating them using wet-lab experiments. This section attempts to provide a broad overview of field.

There are many formalisms for modeling biological systems. The choice of the framework is usually dictated by the biological process under study, the questions for which we seek to gain insights, the experimental data that is available to us for calibrating and analysis of the model and the abstract level of detail at which we seek to gain insights. Models can be built to either give qualitative (Simao *et al.*, 2005; Fisher *et al.*, 2007; Schaub *et al.*, 2007) insights in case the nature of data is limited to qualitative observations or quantitative (Hua *et al.*, 2006; Janes and Yaffe, 2006). On the other hand, model formulation can be deterministic, stochastic or a hybrid between the two paradigms. Common methods of mathematical modeling include Ordinary differential equations (Aldridge *et al.*, 2006), Partial differential equations (Leung, 1989), Boolean networks (Raeymaekers, 2002), Petri nets (Ruths *et al.*, 2008) or Rule-based approaches (Danos *et al.*, 2008) to name a few.

Deterministic vs Stochastic Approaches to Modeling

The most common approach of modeling biological systems is using deterministic kinetics. Deterministic models such as Ordinary differential equations ignore random fluctuations in molecule numbers and other sources of noise. Consequently, given an initial state of the system its dynamics is uniquely determined by the underlying kinetics.

The most widely used deterministic model is Ordinary Differential Equation (ODEs). They capture the concentration changes of different biological players through the reactions they take part in. The concentration of every biological player over time is assumed to be governed by a set of coupled differential equations. The formulation of these equations is dictated by kinetic laws that govern each reaction (Aldridge *et al.*, 2006). Formulating ODEs relevant to biological systems requires one to have a detailed knowledge about the mechanisms of the reactions, rate constants. May times, restricted classes of these models are used by making several simplifying assumptions on the model formalism. Examples include the piecewise – multi affine models (Batt *et al.*, 2008), qualitative differential equations (Trelease *et al.*, 1999).

Stochasticity is important in the context of biological systems especially when considering biological players present in very low particle numbers (such as molecules participating in transcription, translation or their regulation). At these low numbers the effect of randomness in the system is not ignorable and has major implications on function (McAdams and Arkin, 1997). Additionally, cell-to-cell variability can occur due to random events in the cell which can change the order and number of interactions (Elowitz *et al.*, 2002; Spencer *et al.*, 2009). The most popular method for modeling stochastic systems include Chemical Master Equation (Gillespie, 1977) and Rule based formalisms (Danos *et al.*, 2008) to name a few.

Fig. 2 Model Building steps. adapted from Palaniappan, S.K., 2013. Probabilistic verification and analysis of biopathway dynamics. (Dissertation).

Model Construction

Now we will very briefly discuss the main steps involved in building a reliable computational model as described in Fig. 2. Having decided the formalism and the scope of the modeling exercise, we first build the connections/structure of the model which incorporates all our current understanding of the pathway, this can also incorporate any hypotheses that we have. Depending on the data we have at our disposal and the questions to be asked of it, we choose a suitable modeling formalism to model the pathway.

Model Calibration and Tuning

Model calibration and tuning (often referred to as parameter estimation), deals with estimating unknown parameters (such as kinetic rate constants, initial concentrations of unmeasured players) of the model (depending on the chosen formalism). The final goal is to tune the model so that it can explain the given experimental observations. Usually, the experimental data is divided into two sets, one is used for estimating the parameters of model and the other is used as a validation or test set to check for the robustness of estimated parameters or check for overfitting. Model calibration is essentially a mathematical optimization problem where the goal is to minimize an objective function. The objective function is a goodness of fit measure which measures how far away is the model prediction from experimental data. Parameter estimation is a resource intensive task since evaluating the objective function for each parameter combination involves repeatedly simulating the model. After calibration, the model does through a round of model validation where the model output is evaluated for goodness of fit with the test data (which has not been seen by the model yet). If the fit is reasonably good, the conclusion is that the model is not over fitted and has a reasonable predictive power, it can then be used for further analysis tasks, else more calibrations rounds may be necessary or more data may be necessary to train the model.

Model Analysis

Once we have a model that is calibrated, it can be now be used for various model analysis which will help us harness the full potential of the model. Multiple analysis tasks can be performed on the model. For instance, bifurcation analysis gives insights on

the effect of parameters on qualitative behavior of the system. Bifurcation points point to areas along the parameter space where there is a switch in the system behavior and give important insights about how the system switched between states (say diseased and healthy state). It has been used in the context of biological systems for robustness analysis (Morohashi *et al.*, 2002).

Sensitivity analysis (Schoeberl *et al.*, 2008; Rodriguez-Fernandez and Banga, 2008; Rodriguez-Fernandez *et al.*, 2012) on the other hand quantitatively studies the effect of the changes in kinetic parameters or initial concentrations of model players on the dynamic behavior the model. Sensitivity analysis plays an important role in robustness analysis, optimal experimental design, model reduction and drug target selection. In industrial biology and synthetic biology applications they are used for yield improvement where perturbations to the system can lead to target dynamic profile of select biological players.

As we discussed in previous sections, modeling is essentially an iterative process where, as new data or evidence is obtained or when new hypothesis in the mechanisms needs to be incorporated, we will need to re-estimate some parameters or add new links to the model. Additionally, with every change that is done to the model there is a need to verify and validate these models. This ensures that the new model is consistent with what is known already (nothing that is known has changed during the change) and that it explains the new data or hypothesis that has been newly incorporated. Often as the scale of the modeling exercise increases, ensuring that models are in accordance with the current knowledge is a non-trivial task. Manual analysis and validation is error prone.

Automated methods for analysis and verification of these models using Formal methods such as Model checking offers an attractive alternative (Fisher and Henzinger (2007)). The basic idea is to formalize our knowledge about the system behavior either in qualitative or quantitative terms using a specification language called temporal logics. These formal statements are then automatically analyzed against the Model using efficient algorithms to check if the system conforms to them. We can now automatically reason about system behavior and establish the extent to which a given model is consistent with observations of interest. There is a lot of interest in using formal methods for analyzing the dynamics of models in systems biology (Monteiro *et al.*, 2008; Clarke *et al.*, 2008; Hlavacek, 2009). In fact, it has been suggested model checking could serve as yardstick to check the reliability of models in public domain. Formal methods have also been used successfully for model calibration and sensitivity analysis tasks also (Barnat *et al.*, 2012; Calzone *et al.*, 2006; Palaniappan *et al.*, 2013). While there has been considerable effort on Model checking for systems biology, its adoption into mainstream modeling workflows are still limited owing to limited availability of usable tools which can seamlessly connect into a modeler's workflow.

Data Analytics

While the early approaches in computational systems biology focused primarily on modeling of pathways, biochemical reactions and their dynamic simulation in space and time, combining these techniques with data-driven approaches have gained increasing traction in the community. Enrichment analysis based on biological processes, pathways and functions have formed the cornerstone of bioinformatics and systems biology analysis pipelines (Ghosh *et al.*, 2011; Glass *et al.*, 2014).

With the availability of omics-scale data, novel data analysis workflows for gene expression analysis, proteomics and metabolomics analysis have been successfully developed to study the dynamics of those systems (Glass *et al.*, 2014; Khatri *et al.*, 2012; Caron *et al.*, 2017). A recent trend in data analytics for systems biology is the development of multi-omics and trans-omics analysis – methodologies to connect multi-layered data across the omics scale to reconstruct interaction networks linking genetic factors with phenotypes and environmental factors (Yugi *et al.*, 2016).

The rapid rise in machine learning techniques, particularly the class of feature learning convolution neural network models (CNN), known popularly as deep learning architectures, have opened a range of powerful approaches for data analytics in biology (Webb, 2018). Wide-ranging applications of deep learning models have been developed in cheminformatics, translational biomarker and drug discovery, proteomics, to healthcare and clinical informatics (comprehensive reference available at [deeplearning-biology]). Particular success in genomics field including the DeepVariant model for variant calling, enhancer predictions, and population genomics (Poplin *et al.*, 2016).

New horizons in data analytics are opening rapidly and have the potential for far-reaching impact on systems level study of complex biology of health and disease states. The ability to connect the different models and methodologies in a flexible platform (Ghosh *et al.*, 2011), will play a pivotal role in the next generation of computational systems biology applications as we posit next in the conclusion section.

Conclusion

The paper outlines new directions of models and methodologies in computational systems biology ranging from text-mining guided molecular pathway curation to data-driven approaches in network analysis, inference, dynamic modeling and simulation studies.

While early work in systems biology focused on top-down, hypothesis-driven approaches (refer Fig. 1) to model relatively well-defined processes, with the rise of high-throughput omics scale data together with advances in machine learning based approaches, the recent focus has weighted more on data-driven approaches (refer Fig. 1), especially for the applications in medicine and healthcare. Data-driven approaches allow the ability to harness large volumes of data and obtain insights by extracting patterns. Contrary to hypothesis-driven approaches, these techniques do not always require deep knowledge of the underlying biological process which was studied in the experiment and generated the data used in the models. On the other hand, hypothesis-driven approaches embed the biology mechanism in the modeling approach and thus provide better *explainability* of output results compared to pure data-driven approaches, albeit at the cost of injecting a *hypothesis bias* as well as compromise on the model scope

and time to integrate the process information in the models. As we move towards systems medicine, it becomes apparent that a balanced approach which combines the different models and methodologies in a middle-out manner will be critically needed for computational systems biology to empower the future of medicine – the ability to analyze large-scale data to obtain novel insights together with the ability to explain the mechanism of those insights at molecular levels.

Introduction

Traditional biology focuses on structure and function of important biomolecules such as genes and proteins. But this scientific reductionist approach hinders understanding of their interregulation and its role in execution of the various biophysical processes (Joyner and Pedersen, 2011). With the advancement of technologies and exponential growth in data availability, scientists are now probing into the higher order structures that underlie biological activities. This holistic approach has been widening our knowledge about the functionally interdependent molecular circuitry that orchestrates life (Chan and Loscalzo, 2012).

Pathway informatics is a flourishing interdisciplinary research area that is progressively growing and evolving through a blend of computational, experimental, and theoretical approaches (Karp, 2003). This field focuses on understanding how various types of biomolecules interact with each other to form context specific, complex networks, which we often refer to as biological pathways.

To understand the dynamics of biological systems, various computational approaches and pathway databases have been developed, which help in pathway representation, simulation, visualization for quantitative and qualitative analysis (Cary *et al.*, 2005), thus, helping in better understand cellular processes. In this article, we will discuss different biological pathways, their corresponding databases, pathway analysis, and computational approaches for network inference.

Broad Categories of Molecular Pathways

Metabolic Pathways

A metabolic pathway is a series of interlinked biochemical reactions catalyzed by enzymes. Three major classes of molecules in higher order organisms are proteins, lipids, and carbohydrates. Together, these are considered as the building blocks of life. Metabolic pathways that involve synthesis and storage of these biomolecules are referred to as the anabolic pathways. On the other hand, pathways responsible for breakdown of these biomolecules to generate energy are referred to as the catabolic pathways (Ward, 2016).

Regulatory Pathways

Gene regulatory pathways are responsible for turning genes on or off, which in turn determines availability and concentrations of the related protein molecules (Ma and Zhao, 2013). In eukaryotes, genes, by default, are in the off state when they are tightly bound to histones. But eukaryotic genes manage to escape this silencing due to modifications in histones. While histone acetylation makes DNA open and accessible to DNA binding protein, methylation, coupled with histone modification obscure DNA, which in turn lead to gene silencing. Once DNA is open, it is accessible to transcription factors (TFs), which can either transcribe genes or repress them (Hoopes, 2008). Apart from TFs, a number of long and short noncoding RNAs also participate in the ultra-complex gene regulatory network primarily through post transcriptional modifications (Sengupta and Bandyopadhyay, 2011, 2013; Holoch and Moazed, 2015).

Signaling Pathways

Signal transduction is a cascade of biochemical reactions that take place in a cell when a signal molecule such as hormone or biomolecule binds to a receptor on the cell membrane to perform specific biological processes (Pawson, 1995). Cells use a large number of signaling pathways to regulate biological activities. These signals pass information either through protein–protein interactions or via diffusible elements called referred as secondary messengers (Berridge, 2014). Signaling pathway can be of two types: Extracellular and intracellular. The entire signaling process is regulated by feedback pathways (Berg *et al.*, 2002). Any deviation in the signal transduction pathways could cause dysregulation of biological processes and can lead to diseases such as cancer, diabetes, etc. (Liu *et al.*, 2008). Examples of extracellular stimuli are cyclic AMP signaling pathway, voltage-operated channels (VOCs), receptor-operated channels (ROCs), etc. Endoplasmic reticulum (ER) stress signaling, metabolic messengers are the examples of intracellular stimuli (Berridge, 2014).

Drug Related Pathways

Drugs are xenobiotic, small, foreign molecules. To deal with drugs the human body attempts a number of responses. Some drugs are excreted from the body without involving metabolism. But most drugs need structural modification to facilitate excretion,

Fig. 1 Pathway construction by curation.

called drug metabolism. There are numerous pathways through which a drug is metabolized or biotransformed. Chemical processes to metabolize drugs are oxidation, hydrolysis, reduction, hydration, condensation, and conjugation. Study of these pathways as the route of metabolism of a drug can help to assess if a drug shows any pharmacological, clinical relevance, and toxicological activity. The primary site for drug metabolism is the liver (Wilkinson, 2005).

Pathway Construction: Data Curation Based Approaches

The curation process of biological networks and pathways involves manual or computer aided curation of information from various structured and unstructured sources, followed by their assembly in a centralized repository. Major steps involved in pathway building are as follows. First step in pathway construction is mining of relevant data from available public and private data sources about biological entities and their interactions. The pathway draft thus obtained is further enriched while accounting for cell, species, and disease type annotations. This specific annotated pathway is then reviewed by domain experts and iteratively updated before finalization (Viswanathan *et al.*, 2008) (see Fig. 1 for the steps).

Increasingly, natural language processing based methods are taking over manual curation processes. Such approaches are capable of automatic extraction of event–entity relationships from literature (Ananiadou *et al.*, 2010). This accelerated curation process reduces time and labor in accumulating experimentally validated relationships, which, in turn, are used in pathway construction (Yu *et al.*, 2013).

Among several methods, one of the simplest and embrasive approach is cooccurrence based literature mining (Li *et al.*, 2006). For example, if breast cancer and *BRCA1* gene cooccur in a sentence, a relationship between them is assumed. However, this system is prone to errors and may not accurately capture all true relationships that may be latently explained through a number of experimental results.

The second approach is rule-based systems, which exploits some frequently observed linguistic motifs, often used in citing biologically pertinent facts. Such systems either use hard-coded patterns or semantic analysis to find about classes of biologically nontrivial facts. Related to this, a commonly used approach is to use inferential statistics or machine learning to classify sentences and documents into classes of interests (Cohen and Hunter, 2008).

A more sophisticated approach is to infer biological association networks (BANs) through Medscan based sentence parsing. Medscan is capable of extracting relations between proteins and various cellular processes/diseases. If information regarding the direction of relation, mechanism of action and effect on a target is present in the same sentence, Medscan can easily understand and interpret the same. Also, this algorithm can identify if a same relationship is portrayed differently by different authors, thereby reduces redundancy.

Pathway Databases

To keep up with the expansion of our knowledge about biological pathways, systematic and periodic archival of the pathway related information is essential. Below is a list of the key pathway related databases, heavily referred to in biomedical research.

Databases for metabolic pathway

Metabolic pathway databases generally contain detailed information about pathways connected as series of biochemical reactions. One of the main database for metabolic pathways is MetaCyc (Caspi *et al.*, 2013). The MetaCyc is an intensively curated, nonredundant, and comprehensive database for both primary and secondary metabolic pathways. The statistical details of this database are shown in Table 1. It contains valuable information about metabolites, reactions, and enzymatic data that have been experimentally validated through extensive literature scoping from all domains of life.

Another popular database in this domain is Kyoto Encyclopedia of Genes and Genomes (KEGG), which is well-integrated reference knowledge base for molecular interaction, reactions, and network relations for metabolism (Kanehisa and Goto, 2000). Relevant statistics for KEGG are shown in Table 2.

Table 1 MetaCyC statistics

<i>Feature</i>	<i>Statistics</i>
Pathways	2,527
Reactions	14,347
Enzymes	11,547

Human Metabolome Database (HMDB) is an open source containing the most comprehensive curated information about human metabolites and human metabolism data (Wishart *et al.*, 2007). It features over 2180 endogenous metabolites and their details gathered from extensive literature scoping. HMDB also contains metabolite concentration data collected from mass spectra (MS) and Nuclear Magnetic resonance (NMR) data analysis. The HMDB is composed of various tools for browsing, extensive searching, and querying.

Gene regulation databases

Gene regulation databases tend to cover information on relationships between TFs and genes regulated by them. These databases have broad coverage of organisms and some of the databases tend to incorporate DNA binding data from high-throughput assays such as chromatin immunoprecipitation (ChIP). Such protein–DNA binding information only indicates that TFs bind to promoters of genes to regulate them but it doesn't provide functional consequences of such binding (Cary *et al.*, 2005). The most prominent gene regulation databases is TRANSFAC. TRANSFAC is a manually curated database for eukaryotic TFs and their genomic binding sites (Wingender *et al.*, 2000). It is an encyclopedia for transcriptional regulation and is an apt tool for extensive genomic analysis to predict potential transcription factor binding sites (TFBSs). Computationally TFBSs are predicted using basic positional weight matrices, which are involved motifs based on the detected nucleotide patterns in a set of TFBSs for the corresponding TF (Mathelier and Wasserman, 2013). More detailed statistics of TRANSFAC are shown in Table 3. The basic structure of TRANSFAC comprises of two domains, one is involved in documenting TFBSs in promoters and enhancers and another domain is involved in describing TFs (Matys *et al.*, 2006).

TRUSST (transcriptional regulatory relationships unraveled by sentence-based text-mining) is a publicly available manually curated database for human TFs target interactions. Approximately 20 million Medline abstracts have been subjected to sentence-based text-mining approach for manual curation of regulatory networks. TRUSST currently covers 8015 interactions amongst 748 TF genes and 1975 non-TF genes (Han *et al.*, 2015).

Table 4 Signaling pathway databases

Database	URL	Description
Biocarta	http://www.biocarta.com	Database of graphs and annotations about signal pathways
KEGG	http://www.genome.ad.jp/kegg	Manually drawn pathway maps of interaction and reaction network
Reactome	http://www.reactome.org	Curated resource of core reactions and pathways
PID	http://pid.nci.nih.gov	Cellular processes and biomolecular interactions assembled into reliable human signaling pathways
STKE	http://stke.sciencemag.org	Information on the components of cellular signaling pathways and their relations to one another, organized into pathways
AfCS	http://www.signaling-gateway.org	A database of cell signaling and protein interaction in pathways and complex reactions
AMAZE	http://www.amaze.ulb.ac.be	A database to manage, analyze, represent and annotate cell signaling information
BIND	http://www.bind.ca	A data platform binding public and patented sequence, interaction, and related information
DOQCS	http://doqcs.ncbs.res.in	A repository of signaling pathways models, biochemical reaction schemes, rate constants, concentrations, and annotations on the models
SigPath	http://sigpath.org	A database having pathways of dynamic signaling

Signaling pathway databases

Signaling pathway databases contain detailed information about cell signaling molecules and their interactions. Some important signaling pathway databases are discussed here.

BioCarta: BioCarta is the interactive signaling pathway database formed by a group of engineers and scientists, having detailed information of individual molecule. Information provided in BioCarta is not updated so it might be outdated now. Pathways figures are available in the website provided in “see Section Relevant Website” (Nishimura, 2001). **KEGG:** KEGG is a collection of manually drawn pathway maps. This database is easy to download but less comprehensive than BioCarta (Kanehisa and Goto, 2000). **STKE:** STKE is a freely accessible database that has general data of cells and some special signals in cells. STKE offers data access through machine-generated interactive pathway diagrams. The information in database is ordered into generalized and specific pathways (Gough, 2002). **AfCS:** AfCS database provides signaling pathway map and interactions based on molecule interaction (Gilman *et al.*, 2002). **AMAZE:** AMAZE database provides an object-oriented platform, gene regulation entries, cell signaling pathways, and interaction information (Lemer *et al.*, 2004). **DOQCS** and **sigPath** are quantitative signaling pathway databases. **DOQCS** includes rate constants, reaction schemes, concentrations, as well as annotations on the models (Sivakumaran *et al.*, 2003; Campagne *et al.*, 2004).

Some important signaling pathways databases, URLs, and a short description are given in Table 4.

Drug pathway databases

Drug pathway databases contain detailed drug data, drug target information, pharmacological information about drugs, mechanism of action, and metabolism of drugs. Some important signaling pathway databases are discussed here.

DrugBank: DrugBank database is a unique resource of cheminformatics and bioinformatics that combines detailed drug data with complete information on drug targets. Latest updated version (version 5.0.9, released 2017-10-02) of Drugbank contains 10,500 drug entries in which 1737 are approved small molecule drugs, 103 nutraceuticals, 870 approved biotech drugs, and 5023 experimental drugs (Law *et al.*, 2013). **SMPDB** (Small Molecule Pathway DataBase): This is a visual, interactive database that contains more than 30,000 human small molecule pathways. Majority of these pathways are only found in SMPDB. Each small molecule in SMPDB is hyperlinked to complete information in DrugBank and HMDB (Frolkis *et al.*, 2009). **KEGG:** KEGG is an integrated database resource that contains 16 main pathway databases. The health information category of KEGG includes DRUG, DISEASE, ENVIRON, and DGROU databases for drug and disease information (Kanehisa and Goto, 2000). **Transformer:** Transformer is a comprehensive database providing information on transport and transformation of drugs, phase-I and phase-II reactions, alimentary, and traditional Chinese medicine compounds (Hoffmann *et al.*, 2013). **Drug-Path:** Drug-Path is a database generated by KEGG pathway consisting of drug-induced pathway enrichment analysis for drug-induced downregulated and upregulated genes that are coming from datasets of drug-induced gene expression in Connectivity Map. Pipeline of this database relies on information provided by pharmaceutical partners. This provides user-friendly interfaces to download, retrieve, and visualize drug-induced pathway data. In addition, deregulated genes by a given drug are highlighted. The DrugPath database contains information on 2081 drugs, 751 companies, and 722 targets (Zeng *et al.*, 2015).

Other databases

WikiPathways

WikiPathways is a collaborative platform and freely available manually curated public resource for capturing and publicizing models of biological pathways for data curation, visualization, and analysis (Kutmon *et al.*, 2015). It provides you with the

facilities of zoomable pathway viewer, provision for pathway annotations, and convenient hyperlinks to pathways and their components, thus enabling biologists to capture their productive, intuitive mental models of biological pathways without any hassle. The most observable feature of WikiPathways is the pathway page. Each pathway has its own dedicated page providing information about the specific biological mechanism and pathway diagram, along with description and hyperlinks to genes, proteins, or metabolites for detailed information (Kelder *et al.*, 2011). It was launched in 2008 and since then it has seen a massive increase in its content, which is continuously evolving and benefiting the scientific community in several ways (Kutmon *et al.*, 2015; Kelder *et al.*, 2011). Initially, it started out with 500 pathways spanning across 6 species. But today it contains over 2300 pathways spanning over 25 different species. The human pathway coverage is the largest and most active collection by species. This database is quite flexible to use as there are no restrictions on pathway models, therefore accepting any pathway that researchers find valuable in their work. Collection of pathways in WikiPathways are in a format that can be directly and easily used for downstream data analysis using various software tools such as PathVisio and Cytoscape (Kelder *et al.*, 2011). WikiPathways will keep continue to grow, helping researchers across the globe and capturing each and every biological pathway of interest and publicizing it in as many useful ways as possible (Kutmon *et al.*, 2015).

Small molecule pathway database

SMPDB is a freely available manually curated comprehensive, interactive, and visual database intended to carry out clinical omics studies with ease, with specific focus on clinical metabolomics (Frolkis *et al.*, 2009). SMPDB covers over 600 human pathways of small molecule metabolism or processes central to small molecules and nearly 75% of these pathways are not found in other databases such as KEGG, Reactome, and WikiPathways (Jewison *et al.*, 2013). Pathways covered in this database are metabolic pathways, small molecule disease pathways, small molecule drug pathways, and small molecule signaling pathways.

It is the only pathway database that embraces substantial numbers of metabolic disease and drug pathways. SMPDB keeps on adding new information, describing each pathway in the milieu of human physiology and human biochemistry. Also, each drug or metabolite in SMPDB is hyperlinked, which provides detailed information about that particular molecule. In its pathway diagrams, it provides valuable and useful graphical content, which includes the depiction of the organelles, cofactors, and other important cellular features. SMPDB possesses a number of useful, user friendly, and unique features such as use of thumbnail images to facilitate easy pathway viewing and browsing and scrollable table for displaying pathways and pathways synopsis. Although SMPDB work is still in progress, new pathways are constantly being added and existing ones are continuously being improved. Therefore, SMPDB is a useful addition to a collection of already existing pathway databases (Frolkis *et al.*, 2009).

Reactome pathway database

Reactome is an open source of manually curated and peer-reviewed pathway database of human pathways, reactions, and processes. The Reactome data model streamlines the concept of reaction by taking into consideration transformations of different biological entities such as proteins, nucleic acids, and macromolecular complexes. These transformations could be the transport of biological entities from one compartment to another and formation of complexes. Thus, streamlining of Reactome reaction model allows capturing a range of biological processes that span across signaling, metabolic, transcriptional regulation, and apoptosis in a single integrated platform in a computationally navigated format. Reactome is a complete and comprehensive resource of human pathways for facilitating basic research, genomic analysis, pathway modeling, and analysis (Croft *et al.*, 2010).

Pathway Construction: Quantitative Approaches

For obvious reasons curation based approaches lack comprehensiveness. Use of computational and mathematical models is therefore inevitable. Quantitative approaches to model biological pathways can be broadly split into three categories:

- a. Network-based methods
- b. Mathematical modeling

Below we elaborate on the above mentioned categories.

Network-Based Methods

Network-based methods use graph theoretical representation of molecules and their interactions. Nodes in such graphs denote molecules, whereas edges denote their regulatory relationships. Probabilistic graph models are a commonly used technique for modeling molecular interdependencies as observed from genome wide molecular profiling data. Gene expression data is commonly used for such modeling.

Gene coexpression networks (GCN) are progressively being used to model the coexpression relationships among genes. Within a GCN, genes are represented by nodes and edges exists between pair of genes when their expression profiles are significantly correlated across a set of expression-measurement samples (Ficklin *et al.*, 2017). Coexpression analysis network identifies set of genes that have tendency to display a synchronized expression pattern across a group of samples. Coexpression network

construction involves use of different measures for covariability. Pearson's/Spearman's correlation coefficients, mutual information, etc., are popular among these. Coexpression network construction is often followed by identification of community of coexpressed genes using different clustering techniques (van Dam *et al.*, 2017).

Mathematical Modeling

Mathematical modeling of biological processes arises with deep knowledge of complex cellular systems (Wang *et al.*, 2012). Mathematical models learn and analyze the principal network and then convert the reactions and entities of underlying network into matrix form. To study biological pathways, complexity of networks, and different type of biochemical reactions, a number of mathematical methods have been developed (Hou *et al.*, 2015). Below we provide an excerpt of these methods for modeling signaling, regulatory, and metabolic pathways respectively.

Signaling pathways: Signaling pathways are studied in either top-down or bottom-up fashion. Top-down approaches work on omics datasets to infer downstream biological processes. On the other hand, bottom-up approaches are used to model the interaction between the biological components such as proteins, genes, and metabolites to learn about the dynamic behavior of the cell. The most widely used bottom-up approach is continuous dynamic modeling, which needs adequate kinetic parameters (synthesis and degradation rates) and mechanistic details. Discrete dynamic modeling, for example, Petri nets, Boolean network models, and multivalued logical models yield qualitative dynamic illustration of a system behavior that does not need kinetic parameters (Liu and Betterton, 2012; Wang *et al.*, 2012).

Regulatory network: Understanding the dynamism of regulatory networks is critical in understanding the mechanism of diseases that occur due to dysregulation of these regulatory networks (Karlebach and Shamir, 2008). Differential equations can be used to represent these regulatory networks, in which interactions among proteins, mRNAs are defined in terms of rate equations. As the system evolves, these rate equations specify the levels of each mRNA and protein as a function of other components. Differential equation based models use time and/or space dependent variables (mRNA and protein concentration, production rate, degradation rate).

These models can be divided into two groups:

- Ordinary differential equations (ODE), which involve a single variable such as time.
- Partial differential equations (PDE), which depend on more than one variable such as time and space.

Finding analytical solutions for ODEs is hard. Approximate solutions can be found by various approximate numerical methods (Ay and Arnosti, 2011).

Differential equations have been used in modeling regulatory networks in various organisms:

- In bacteriophage T7 developmental cycle (Endy *et al.*, 2000)
- Tryptophan synthesis in *E. coli* (Santillán and Mackey, 2001)
- In *E. coli* lac operon induction (Carrier and Keasling, 1999)
- Cell division in *Xenopus* (Novak and Tyson, 1993)
- Circadian rhythms in *Drosophila* (Leloup and Goldbeter, 1998)
- In lytic and lysogenic cycle of bacteriophage (McAdams and Shapiro, 1995)

Metabolic pathway: Mathematical interpretations of protein and gene expression, developmental biology, and enzyme kinetics are required to understand the control system that underlies metabolic flux. To design a mathematical model for metabolic pathways, dynamic mathematical models of metabolic networks and stoichiometric models and flux analysis are used. Dynamic models are designed to predict how metabolism will respond to genetics as well as environmental manipulations. Stoichiometric models and flux analysis are largely used and descriptive models, which gives the complete description of metabolism. The former is a purely descriptive tool that yields detailed quantitative snapshots of metabolism that could be employed to gain insight into physiology. The latter class of tools (e.g., dynamic models) move from the realm of description to potential prediction as to how metabolism will respond to manipulation, either environmental or genetic. Flux balance analysis (FBA) is a control based modeling method that can be used to produce computational models by integrating transcriptomic data into metabolic network regenerations. Metabolic flux analysis (MFA) is a well-known method to study metabolic flux in microorganisms but it is still a challenge to adapt these methods for a complex eukaryotic system. MFA has been used to study how various factors (genetic or environmental) and conditions can affect cellular metabolism in fungi. In mammalian cells, MFA is also used to in medical studies, toxicological research, and cell culture techniques.

A flowchart for pathway modeling is given in Fig. 2.

Some Common Applications of Pathways

Pathway analysis methods possess a wide range of applications in biomedical research. They help researchers to figure out important biomolecules, which are key in understanding the phenomena under study. Pathways also help in pathology specific determination of biological function of candidate genes, of which many have therapeutic value. Another application of pathway analysis is that it helps in the determination of functional similarities and dissimilarities between samples based on differential molecular abundance. In summary, pathway analysis is an indispensable tool for data driven sectors in biomedical and cell sciences.

Fig. 2 Template for quantitative approaches for pathway construction.

Overrepresentation Analysis

Overrepresentation analysis (ORA) or functional enrichment analysis approach is routinely used in functional genomic studies to identify overrepresented pathways with a list of interesting or susceptible genes, genes that are likely to increase the likelihood of developing particular disease by using traditional statistical tests such as Fisher's exact test for contingency table (Jin *et al.*, 2014). ORA involves creating an input gene list based on certain criteria, which is followed by counting the number of genes in the list of susceptible genes that hit the gene set annotated by Gene Ontology, KEGG, BioCarta, and Reactome. This is followed by assessing the significance of overlaps using traditional statistical tests and finding out relevant pathways based on their *p* values. Although it is a widely used method there are certain limitations, in that it does not take into account complex gene–gene interactions and secondly it assumes that each gene is of equal importance, which is not the case in biology (Dong *et al.*, 2016). It is not suitable to use ORA when genes to be analyzed are very large as it is based on a stringent threshold. Its statistical power is low when GWAS data is used for identification of significant genes (Jin *et al.*, 2014).

Gene Set-Based Scoring

Gene set-based scoring methods are an extension of ORA but they don't assume that each individual gene is of equal importance; rather they rank these genes by some statistical criteria or *p* values. They are different from ORA in two ways. Firstly, they remove criteria of using an arbitrary threshold as used by ORA and thus consider all of the genes in an experiment. Secondly, they permute phenotype class labels to assess the significance and they allow preserving of gene–gene correlation, thus resulting in a more accurate null model. Statistical tests such as Wilcoxon rank sum or Kolmogorov–Smirnov can be used to know the overall impact of a gene set on biological phenotypes (Jin *et al.*, 2014).

One of the applications of gene set-based scoring is in gene set enrichment analysis (GSEA), a powerful method for inferring results of gene expression data at a level of gene sets. This method is quite powerful since it focuses on gene sets, i.e., genes sharing common biological functions chromosomal location or regulation. Gene sets are defined based on prior biological knowledge such as published biochemical pathway data or other coexpression experimental data. Ranking of genes is based on the correlation between their expression and class distinction can be done by using any suitable metric. The aim of GSEA is to determine whether the majority of genes from a gene set falls towards the top or bottom of the list and in which case the gene set can be correlated with the disease phenotypes. Main steps involved in GSEA are:

- Calculation of enrichment score (ES): ES represents degree to which gene set is overrepresented at the extremes (top or bottom) of the entire ranked list. This score corresponds to weighted Kolmogorov–Smirnov like statistics.
- Estimation of significance level of ES: Statistical significance is estimated by empirical phenotypic based permutation test procedures in order to generate a null distribution for the ES.
- Adjustment for multiple hypothesis testing: When a large number of gene sets are being analyzed at one time, ES for each gene set is normalized, and false discovery rate is calculated (Subramanian *et al.*, 2005).

Network Topology-Based Analysis

Topological analysis is involved in identification of global qualitative properties of the biological system. Most methods in topological analysis are developed for analyzing gene expression data, and they virtually can be extended to other data types (e.g., GWAS)

fairly easily. They combine conventionally measured molecular data and also the structural information of the pathway provided by biological databases. Classical graph theory is used by one approach to identify several motifs, which are groups of interacting biological entities capable of processing information that occurs repeatedly in a pathway and are represented as a directed graph. Boolean network analysis can be used to identify feedback loops, i.e., impact of negative or positive regulations of each interaction. Bayesian networks can also be used for inferring indirect relationships and studying complex cellular networks from quantitative experimental data (Viswanathan *et al.*, 2008). Two algorithms based on topological based analysis are:

ClipPER: ClipPER is an empirical two-step method based on Gaussian graphical models that tries to identify signal paths within significantly altered pathways. First step in ClipPER is testing of the whole pathway. Under specific conditions, strength of molecular interactions within a pathway could be transformed (Martini *et al.*, 2012). The P value of the test defining whether two graphical Gaussian models (cases and control) are homoscedastic as the weight is collected to compute the relevance of each path (Jin *et al.*, 2014). Second step involves identification within these pathways the signal paths having the greatest association with a specific phenotype (Martini *et al.*, 2012).

Signaling Pathway Impact Analysis (SPIA): SPIA is topology-based pathway analysis method that combines two types of evidence, classical enrichment analysis and actual perturbation on a given pathway (Tarca *et al.*, 2008). It is involved in the capturing of several features of data such as changes in gene expression, the pathway enrichment, and the topology of signaling pathways (Jin *et al.*, 2014). In order to assess the significance of the observed total pathway perturbation, a bootstrap procedure is used (Tarca *et al.*, 2008). This method models signaling pathways as a graph where nodes are represented by genes and edges represent interactions (Jin *et al.*, 2014). Furthermore, it defines a gene-level statistics and pathway level statistics, which is called perturbation factor (PF). The PF for a gene is defined as a sum of its measured change in expression and a linear function of the PFs of all genes in a pathway. PF in case of pathway is defined as a sum of PFs of all genes in a pathway (Tarca *et al.*, 2008).

Conclusion

Pathway analysis has emerged as an indispensable tool in functional genomics studies. It is routinely being used in generating biological hypothesis testing on the premise of quantitative molecular investigations. With the accumulation of underanalyzed genomic data deluge an unprecedented opportunity has been created to accelerate pathway research. The role of big consortia is felt in managing goal oriented crowd-sourced projects for expanding and crystallizing our knowledge about biological pathways.

Also, for a better interoperability of multiple software systems and data types, pathway databases must adopt common data standards and formats as it is highly desirable to combine data from different pathway databases. This will allow better coverage of all the reactions and biological entities involved in a pathway (Bauer-Mehren *et al.*, 2009).

In summary, advancement in the field of pathway informatics together with next-generation sequencing technologies presents an unparalleled opportunity for fully exploiting the power of pathway database and pathway analysis resources, tools, and software for understanding cell and disease biology better.

Introduction

Biological networks inference, also referred to as ‘reverse engineering’, is the scientific process of using (low- and high-throughput) experimental data, statistical and computational techniques to reconstruct how the elements of the biological network (genes, proteins, signaling molecules, cells) interact and operate as a system.

The paradigm of ‘network’ is crucial for the sciences of complexity, as well as for systems biology. This concept represents a potent instrument for the description and analysis of complex systems, their elements and their connections, able to detect underlying topologies, structures, architectures as well as functions emerging from the arrangement of their components. Such methodology has been fruitfully employed for the representation and for the analysis of numerous different systems in various fields of study, e.g., engineering and technology, social studies and, of course, life sciences.

The power of the network approach basically resides in the capability to catch specific features of any type of systems, e.g., steady and/or physically connected systems (such as the physical internet cabling, or power grids) as well as dynamic, virtual and non-cabled (such as social networks, air traffic networks, or gene/protein interactions).

In bioinformatics, such interdisciplinary approach allowed to undertake, probably for the first time, rigorous mathematical analysis of larger portions of, or even whole biological systems.

A critical step is therefore the process of reconstruction of such networks starting from accessible data. Here, making no claim to completeness, we briefly outline inference and reconstruction approaches of some among the most relevant types of biological networks in molecular biology and neuroscience, and some of the most promising methodologies applied in the recent field of network medicine.

Molecular Networks Inference

Protein–Protein Interaction Networks

Protein-protein interactions (PPIs) are highly specific physical contacts, stable or transient in time, between two or more proteins. PPIs involve electrostatic forces between the so-called protein surfaces, i.e. the ‘exposed’ regions of the three-dimensional structures of folded proteins. PPIs are essential to almost every process in a biological system, e.g., in signal transduction, cell metabolism, membrane transport, muscle contraction, among others, and consequently their mapping and understanding is critical for the comprehension of cellular physiology in normal and as well as in pathological conditions.

The representation of interconnected webs of PPIs at the cellular level, or, in other words, the union of all considered proteins and the interactions among them, are generally referred to as protein interaction networks (PINs). Such networks are usually represented with undirected graphs and undergo mathematical and computational analysis in order to study cell processes, functions and organization at the system level.

PINs reconstruction is carried using several experimental (in vivo and in vitro) and computational methods, involving specific and different pros and cons (Rao *et al.*, 2014; Cafarelli *et al.*, 2017).

Among the most widely known experimental approaches, Yeast 2 hybrid (Y2H) is an *in vivo* method, suitable for both transient and stable interactions. It is implemented by screening the protein of interest against a library of potential interacting protein partners through the activation of a reporter gene (usually the gene *Gal4* in the yeast *Saccharomyces cerevisiae*). Y2H is affordable, fast and low-tech, but recently it has been criticized as not completely reliable in terms of yielding high numbers of false positive identifications. Y2H is the only *in vivo* method based on the detection of real physical interactions, being the other *in vivo* one, namely synthetic lethality, based on functional interactions, i.e. using deletions or mutations in genes to observe protein interactions.

Among the most used *in vitro* techniques, tandem affinity purification-mass spectroscopy (TAP-MS) is based on labelling the protein under scrutiny on its chromosomal locus with a designed protein tag, and on a two-step purification method followed by mass spectroscopic analysis. It is usually considered suitable for stable interactions only (due to the purification steps), simple to implement and quantitatively reliable. Other approaches include protein microarrays, affinity chromatography, coimmunoprecipitation, X-ray crystallography or NMR spectroscopy, among others.

Among the *in silico* methods, the ortholog-based sequence approach is a commonly used technique: it is grounded on the homologous nature of the query protein in the annotated protein databases using pairwise local sequence algorithm. Other *in silico* approaches are based on protein sequence (as the summentioned ortholog-based one) or protein structure, on gene fusion or gene expression, on chromosomal proximity, on phylogenetic tree or gene ontology.

Methods for the assessment of PPIs, among other approaches, can be implemented computationally e.g., by using specific reliability indexes such as 'expression profile reliability' (EPR) index (used to assess whole datasets by comparing the RNA expression profiles for the proteins whose interactions are found in the screen with expression profiles for known interacting and non-interacting pairs of proteins) or the paralogous verification method (PVM, used to score individual interactions), which judges an interaction likely if the putatively interacting pair has paralogs that also interact. PPI validation can be also implemented by using known macromolecular complexes that provide defined and unbiased set of protein interactions (Przulj, 2011). It is foreseen that prospective PIN reconstruction attempts will focus on the dynamic and quantitative properties, surpassing current stationary representations (Cafarelli *et al.*, 2017).

Gene Regulatory Networks

Gene regulatory networks (GRNs, also known as transcriptional regulatory networks) are networks of causal interactions among transcription factors and downstream genes, and are usually represented with directed graphs and inferred by gene expression data. Links between elements of a GRN represent biochemical process such as a reaction, transformation, interaction, activation or inhibition. GRNs are a crucial area of systems biology research, providing understanding of the inward mechanisms of a biological system.

Many methods to infer GRNs are based on mutual information (MI) (e.g., MI with background, maximal MI, conditional MI, three-way MI), a probabilistic concept and dimensionless quantity that states how much the knowledge of a random variable tells about another one: in other words, mutual information can be thought as the decrease in uncertainty of a random variable once given knowledge of another, so that mutual information equal to zero between two random variables means that the variables are completely independent (nothing can be said about a variable given the other), and increases of mutual information denote decreases in such uncertainty.

Inferred GRNs represent causal biochemical interactions between genes, RNA and proteins which links aim to correspond to real physical, directed, and quantitatively determined interaction events between such molecules that can potentially lead to the discovery of, for example, crucial functional relationships between RNA expression and chemotherapeutic susceptibility (Butte *et al.*, 2000). Recently, data from single-cell gene expression have become mature and have been approached using partial information decomposition to detect putative functional associations and to formulate systematic hypotheses (Chan *et al.*, 2017; Aibar *et al.*, 2017).

The validation of GRNs implies the definition of 'gold standards' (i.e. sets of interactions validated with a given level of certainty) and the use statistical thresholds to quantitatively evaluate the adherence of the GRN to such standards, or perturbation analysis of the biological (sub)system to observe and measure perturbation effects and subsequently validate the network under scrutiny (Chai *et al.*, 2014; Hecker *et al.*, 2009; Emmert-Streib *et al.*, 2014; Veiga *et al.*, 2010; Lee and Tzou, 2009; Bansal *et al.*, 2007).

Gene Co-Expression Networks

Gene co-expression networks (GCNs) are transcript–transcript association networks, generally reported as undirected graphs, where genes are connected when an appreciable co-expression association between them exists.

GCNs are built from gene expression data by calculating co-expression values in terms of pairwise gene similarity score and choosing a significance threshold. Debates on normalization methods, co-expression correlation (e.g., based on Pearson's or Spearman's correlation measures, among others) and significance and relevance are still alive and ongoing. Graphical Gaussian Models (also said 'concentration graph' or 'covariance selection' models) are also popular in the field of GCNs, the key idea behind them being the use of partial correlations, able to discriminate between direct and indirect interactions, as a degree of independence of any pair of genes (Schafer and Strimmer, 2005). Other strategies for GCN inference include edge removal based on gene triplets analysis (e.g., ARACNE) (Margolin *et al.*, 2006), regression methods and Bayesian networks (aimed to discover the best gene set predictor of a target gene expression).

GCNs are a potent approach to gather biologically relevant information, e.g., for the identification of genes not yet associated with explicit biological questions, and for accelerating the interpretation of molecular mechanisms at the root of significant biological processes. Trends in this field include, among other approaches, the combination of co-expression analysis with other omics techniques, such as metabolomics, for estimating the coordinated behavior between gene expression and metabolites, as well as for assessing metabolite-regulated genetic networks (Serin *et al.*, 2016; Usadel *et al.*, 2009).

Metabolic Networks

Metabolism, apart from obviously being the set of life-sustaining biochemical reactions in every organisms, is also among the major contributors to many human diseases, such as cardiovascular diseases, obesity, diabetes and cancer, to cite some. Metabolic network reconstruction is commonly referred to as the annotation process of genes and metabolites for the determination of the metabolic network's elements, relationships, structure and dynamics. It is generally possible to infer the enzymatic function of individual proteins, or to reconstruct larger (or whole) metabolic networks in their entirety.

Originally introduced at the beginning of 1900, the first successful attempts to quantitatively reconstruct small metabolic networks, involving linear sequences of few reactions, date back to the Eighties of the past century. Later on, coordinated efforts led to the reconstruction of the global human metabolic network, based on recent genome annotation and on a large amount of bibliomic data (Mo *et al.*, 2007). Today, the main aim is usually the reconstruction of genome-scale metabolic networks, and techniques such as metabolic flux analysis (MFA) and its enhancements (e.g., isotopically nonstationary metabolic flux analysis), and flux balance analysis (FBA) has become widely used for the simultaneous predictions of fluxes of multiple reactions. The methods are generally based on stable isotope-labeled substrates and measuring time courses of intracellular metabolites labels. FBA is able to generate flux predictions without prior information of enzyme-kinetic parameters, based on optimization principles that theoretically should have shaped efficiency (and fluxes) of metabolic networks. Integrated computational approaches coupling metabolic flux analysis with mass spectrometry approaches have been also recently used. From the computational side, single enzyme function prediction is carried out by using machine learning (e.g., when the enzyme does not show significant similarity to existing proteins from which predictions can be made) or the so-called ‘annotation transfer’ approaches (based on DNA sequences or reference databases or orthologs, to predict the occurrence of enzymes). Comparative pathway prediction techniques generally use existing functional annotations to check for the presence of new reactions, while explorative pathway prediction approaches, i.e. without the use of existing annotations, can be graph-theoretic (e.g., by weighting paths of metabolite connectivity) or constraint-based (e.g., elementary mode analysis), or both (Pitkanen *et al.*, 2010; Nikoloski *et al.*, 2015).

Signaling Networks

Signaling networks are cascades of molecular interactions and chemical modifications to carry stimuli (e.g., signaling molecules, hormones, pathogens, nutrients) sensed by cell membrane receptors down to the nucleus to coordinate initiate proper metabolic and genetic responses. The processes of identifying signaling networks constituents and of network reconstruction have been often carried out by using gene knockout techniques, which have been effective in describing cascades in a linear manner. Nevertheless, the complexity and intricate nature of such networks require new methods that can infer aspects and features of signaling processes from high-throughput omic data in a faster and systemic way. In this perspective, efficient algorithms are necessary to analyze and detect relations among numerous data points, and in general such inference problems can be reported to the definition of suitable optimal connected subgraphs of a network originally defined by the available data, which can result in being computationally intractable. Some of the approaches employ Steiner tree approaches (e.g., based on the determination of the shortest total lengths of paths of interacting proteins), or linear programming and maximum-likelihood (e.g., based on tagging proteins as activators or repressors to explain the maximum number of observed gene knockout); other use probabilistic network approaches, such as network flow optimization (e.g., based on Bayesian weighting schemes for underlying PPIs coupled with other omic data), or network propagation (e.g., based on a gene prioritization function that scores the strength-of-association of proteins with a given disease), or information flow analysis (a computational approach that identifies proteins dominant in the communication of biological information across the network) (Tuncbag *et al.*, 2013; Ourfali *et al.*, 2007; Missiuro *et al.*, 2009; Huang and Fraenkel, 2009; Aldridge *et al.*, 2006; Papin *et al.*, 2005; Ritz *et al.*, 2016; Molinelli *et al.*, 2013; Hyduke and Palsson, 2010)

Assessment and Validation of Inferred Molecular Networks

The methods to reconstruct biological networks as well as inferred networks need to undergo rigorous validation and assessment processes based on theoretical points, on *in silico* experiments, and on ‘wet lab’ data. Known issues about assessment approaches include the volume of information accessible related to the network entities, the general sparseness of biological networks as well as their topology, and, often neglected, the lack of experimentally verified non-interacting pairs. Some general considerations arise, applicable to the different types of networks and of methods. As a general procedure, network inference methods have been often assessed using receiver operating characteristic (ROC) curves and precision-recall (PR) curves: being them differently sensitive to the ratio between (true/false/actual/predicted) positives and negatives among the tested pairs, ROC curves seem to show and advantage in comparing different classification methods (Schrynmackers *et al.*, 2013). Another general consideration regards the relevance of the lack of experimental support for non-interacting pairs in most biological networks, especially in the field of PPIs, lack that can heavily impinge upon the assessment of false positives, issue that is recently receiving more attention (Blohm *et al.*, 2014; Smialowski *et al.*, 2010; Launay *et al.*, 2017; Srivastava *et al.*, 2016). Some specific measures have been used to assess inferential validity for GRNs, such as the Hamming distance (e.g., to measure the network topology closeness), or steady-state mass difference for network dynamic behavior similarity (Qian and Dougherty, 2013). As a general consideration, the challenging nature of network inference tasks should be highlighted, as a remarkable amount of the evaluated algorithms seems to not accomplish better results than random (Lopes and Bontempi, 2013; De Smet and Marchal, 2010), but it is also recognized that despite inferred networks might not be error-free at the level of mechanistic description, they can still be fruitfully used to comprehend emergent functions and behavior of biological systems (Stolovitzky *et al.*, 2007).

Networks in Neuroscience

In neuroscience, network science can be applied to the patterns obtained by studying the brain anatomy and activity at different spatial (molecules, neurons, circuits, whole brain, social behavior) and temporal scales (milliseconds, minutes, hour, days, years). Examples

include networks like those described above (PPI, genetic regulatory networks...) and networks consisting of anatomical or functional connections among brain areas. The concept of functional brain connectivity is crucial to understand how communication between cortical regions is organized: brain areas interacting with a functional connection are not necessarily connected by a direct physical link; on the other hand, an anatomical link does not necessarily imply that a functional connection has established at any time point.

Anatomical connectivity can be tracked by diffusion weighted imaging techniques such as Diffusion Tensor Imaging (DTI): this technique shows anatomical connections of neurons by identifying nerve fiber pathways in the brain.

Brain functional connectivity can be estimated from a wide range of biomedical signals and with different neuroimaging techniques – functional magnetic resonance imaging (fMRI), electroencephalography (EEG), magnetoencephalography (MEG), positron emission tomography (PET). In the following a description of two of the main approaches is provided.

- **Functional magnetic resonance imaging (fMRI)** is a specific magnetic resonance imaging procedure to measure brain activity by detecting associated changes in blood flow: specifically, brain activity is measured through low frequency blood oxygenation level dependent (BOLD) signal in the brain. fMRI technique is characterized by high spatial resolution, but by poor time resolution.
- **Electroencephalography** is a method to record electrical activity of the brain. Scalp EEG data have many advantages: high temporal resolution, non-invasiveness and low-cost. On the other hand, it is characterized by low spatial resolution. An EEG setup can be used in a wide range of pathological conditions and can be easily adapted to different clinical settings. To overcome the limitation of the low spatial resolution, in the past decades, the inverse EEG solutions has received considerable attention: this approach provides estimation of source distributions within the brain that correspond to the scalp-recorded signals. Different methods (e.g., minimum norm estimates (MNE), low resolution electrical tomography (LORETA), beam-forming approaches) have been proposed to solve the EEG inverse problem (Grech *et al.*, 2008). Once the inverse problem for EEG source localization is solved, connectivity estimation can be performed in the source space.

Three classes of methods are commonly used to estimate functional connectivity:

- **Model-based functional connectivity approaches.** Seed based connectivity is a hypothesis-driven method based on a priori decision regarding the regions of interest (ROI). It is usually adopted with fMRI data. *Methods based on Granger causality* (Granger, 1969) also belong to this class. They are defined both in time and in frequency domain, and being based on bivariate or multivariate autoregressive models they allow to reconstruct the direction of information flows. Examples of Granger Causality-based methods are: i) *Partial Directed Coherence* (Baccalá and Sameshima, 2001); ii) *Directed Transfer Function* (Kamiński and Blinowska, 1991); iii) *time reversed Granger Causality* (Haufe, Nikulin, and Nolte, 2012).
- **Model-free functional connectivity approaches.** These methods are especially useful in the analysis of spatially distributed functional connectivity networks. An example is the *imaginary coherence* (Nolte *et al.*, 2004). Coherency between two EEG-channels is a measure of the linear relationship of the two at a specific frequency. The idea is to isolate the imaginary part of the coherency which reflects interactions. This method does not return the information about interaction direction and it has been proposed as a possible solution to the interpretation of observed interactions between time series when they are affected by volume conduction.
- **Biologically Inspired models.** *Dynamic Causal Modelling* (DCM, (Friston *et al.*, 2003)) belongs to this class. DCM is a general framework for inferring processes and mechanisms at the neuronal level from measurements of brain activity with different techniques (fMRI, EEG/MEG, etc.): it combines a model of the hidden neuronal dynamics with a forward model that translates neuronal states into predicted measurements. This method returns directed networks.

In the last decades, several studies demonstrated that by combining neuroimaging techniques (functional MRI, EEG, etc.) with network science, it is possible to characterize the topological properties of human brain networks. Nowadays, network characterization of structural or functional connectivity data is increasing (Bassett and Sporns, 2017; Bullmore and Sporns, 2009) and rests on several important motivations. Indeed, complex network analysis promises to reliably quantify brain networks with a small number of neurobiologically meaningful and easily computable measures (Pichiorri *et al.*, 2017; Petti *et al.*, 2016; Achard and Bullmore, 2007; Toppi *et al.*, 2012).

Network Medicine

Until recently, the investigation of disease etiology, diagnosis and treatment, has been based on a conventional reductionist approach. This tenet argues that critical biological factors work in a simple linear mechanism to control disease pathobiology. Rather, they are nearly always the result of multiple pathobiological pathways that interact through an interconnected network: a disease is rarely a direct consequence of an abnormality in a single gene or molecular component (Chan and LoScalzo, 2012). For example, complex diseases like hypertension, atherosclerosis or cancers of various sorts, have extraordinary complex biological phenomena that underlie them.

Today, big data, genomics, and quantitative *in silico* methodologies integration, have the potential to push forward the frontiers of medicine in an unprecedented way. Clinicians, diagnosticians and therapists have long strived to determine single molecular traits that lead to diseases. What they had in mind was the idea that a single “golden bullet” drug might provide a cure. But, this reductionist approach, largely ignored the essential complexity of human diseases. Indeed, a large body of evidence that is now emerging from new genomic technologies, points out directly to the cause of disease as “perturbations” within the “interactome”, i.e. the comprehensive network map of molecular components and their interactions. The interactome integrates all physical

interactions within a cell, from protein-protein, regulatory protein-DNA and metabolic interactions. Currently, more than 140,000 interactions between more than 13,000 proteins are known.

Consequently, a paradigm shift is needed towards the development of temporal and spatial multi-level models, from molecular machineries to single cells, whole organism and individuals, including the environment, to reveal the underlying links among components. This new type of medical paradigm is called “Network Medicine”. Rather than trying to understand pathogenesis into a reductionist framework, network medicine entwines the many facets of disease in many different types of networks: from the physical interactions acting in a cell to the information flow through biological components. The human genome sequencing using high-throughput next-generation devices is being deeply affecting current conceptions of biomedical and clinical research. More recently, entering the era of personal whole-genome sequencing, 38 million genetic variants some of which are rare mutations and thus may be associated with large size effect.

How to use this big data and information deluge to generate better understanding of disease and find appropriate drug targets? An entirely new perspective is required as a shift from a reductionist to a holistic and data-driven research: looking at networks without a specific biomedical bias in mind and let the data speak by themselves, so to formulate new hypothesis to be further validated by experimentalist and so on, moving within a virtuous circle of shared knowledge. Most importantly, the representation of complex systems as networks is of paramount importance for visualizing the interactome underlying structure, revealing new functional roles, and proposing new and fresh interpretations of data. Networks can be obtained from any sort of information: known protein-protein interactions, gene expression profiles, functional annotation, etc. In fact, the fundamental tenet of network medicine is to look at diseases as perturbations within the ‘interactome’, i.e. the overall network map of molecular components and their interactions. Recently, has been shown the genes associated with a disease are localized in specific neighborhoods, or ‘disease modules’, within such an interactome. The overall ambition of this initiative is to both developing a global understanding of how interactome perturbations result in disease traits, and to translate computational insights into concrete clinical applications, such as new drugs and therapies or diagnostic tools.

A true inter-disciplinary environment for network medicine must be based on the accurate preparation the interactions among experts of different fields, especially from those trained in medical/biological sciences with those experts in data analysis, bioinformatics, statistical modelling, and network algorithms. The gap between the biological and the informational mindset can be daunting and might impair from the beginning the development of shared concepts. However, the network medicine setting will certainly facilitate communications across disciplines given the immediate and intuitive understanding of the “network” concept, a metaphor that can be used by molecular biologists to visualize their knowledge in a structured way ready to be translated into an algorithm on the available data, as medical or biological goals are defined. [Barabási et al. \(2011\)](#) proposed the following research pipeline:

for any specific disease, the identification and validation of disease modules consists of several steps:

- Interactome reconstruction merges the most up-to-date information on protein-protein interactions, co-complex memberships, regulatory interactions and metabolic network maps in the tissue and cell line of interest.
- Disease gene (seed) identification collects the known disease-associated genes obtained from linkage analysis, genome-wide association studies or other sources, which serve as the seed of the disease module.
- In disease module identification, the seed genes are placed on the interactome, with the aim of identifying a subnetwork that contains most of the disease-associated components, exploiting both the functional and topological modularity of the network.
- Pathway identification can be used in instances in which the number of components contained in the ascertained disease module is so large that it cannot serve as a tractable starting point for further experimental work.
- During validation disease modules are tested for their functional and dynamic homogeneity.

Disease Gene Prediction Methodologies

A classification of the disease gene prediction methodologies can be performed following different criteria ([Piro and Di Cunto, 2012](#)):

- Type of evidence: different data sources can be exploited to predict disease-genes (sequence data, protein-protein interactions, gene expression...).
- Level of knowledge: disease-gene prediction methods can be classified based on the use of prior knowledge for example about causal genes for the disease phenotype under investigation or about affected tissues/organs.
- Type of prediction: prediction methods can return a prioritization of the candidate genes (a ranking according to their likelihood of being involved in a disorder) or a selection of best candidates. In the first case the goal is to rank the disease gene as high as possible in the prioritized candidate list, while candidate selection methods provide a candidates’ set (as small as possible).
- Scope of application: based on this criterion, we can distinguish between disease-centered methods and undifferentiated approaches. In the first case, candidates are evaluated in relation to a specific disease (or disorders class), while methods belonging to the second class provide an overall evaluation of the involvement of the candidates in some disease in general.

More recently, the main classification was performed based on network analysis strategy:

- local methods, algorithms based on the search for direct neighbors of disease genes;

- global methods: methods that model the information flow in the cell to assess the proximity and connectivity between known disease genes and candidate genes.

Here we focus on disease-gene prediction methods that are based on the analysis of the topological properties of protein-protein interaction (PPI) networks and we describe with more detail some of the most used and newest approaches at the state of the art.

Local Methods

- **Direct Interaction (DI).** [Oti et al. \(2006\)](#) proposed a procedure to detect disease-genes in known disease loci by exploring the degree to which proteins linked to known disease-genes are also associated with the same phenotype. The algorithm performs the following steps:
 - identification of neighboring proteins for each known disease protein;
 - identification of chromosomal locations of the genes coding for these interacting proteins using gene location data from the Ensembl database;
 - check of the chromosomal locations: each interacting protein gene located within one or more disease loci (of the same disease) was considered a candidate gene prediction;
 - predictions counting: if a candidate gene lay within multiple (overlapping) loci of the same disease, each of them was counted as a separate prediction.
- **GenePANDA (Gene Prioritizing Approach using Network Distance Analysis).** In the last year another algorithm of this class has been proposed: GenePANDA (Gene Prioritizing Approach using Network Distance Analysis) ([Yin et al., 2017](#)). The novelty of GenePANDA is the introduction of adjusted network distance that is derived by considering not only the direct network distance between two genes, but also their respective mean network distances to all other genes in the network. This method uses the STRING network ([Franceschini et al., 2013](#)) and the Genetic Association Database (GAD) as the resource of disease data, and it consists of three steps:
 - adjusted network distance computation: adjusted network distance is computed considering not only the direct network distance between two genes, but also their respective mean network distances to all other genes in the network. Given the genes a and b , their adjusted network distance is defined as:

$$D_{ab}^{adj} = \frac{D_{ab}}{\sqrt{\mu_a \times \mu_b}} \quad (1)$$

where D_{ab} is the raw network distance between gene a and gene b , μ_a and μ_b the mean raw network distances for a and b respectively, defined as:

$$\mu_a = \frac{\sum_{j=1}^N D_{aj}}{N} \quad (2)$$

with N the total number of genes in the network, and D_{aj} the raw network distance between a and b ;

- *disease-specific gene weighting* with the hypothesis that a candidate disease gene should have stronger functional interaction with known disease genes than with random genes in the network. Based on this hypothesis, a disease-specific gene weight was defined as:

$$w_i = \frac{\sum_{j=1}^N D_{ab}^{adj}}{N} - \frac{\sum_{j=1}^K D_{ab}^{adj}}{K} \quad (3)$$

where N is the total number of genes in the network, K is the total number of disease genes. Higher weight indicating higher probability to be a candidate disease gene.

- score conversion: for a given disease, the disease-specific gene weights can be compared with each other related to the same disease, but they cannot be directly compared across diseases. To overcome this limitation, a score conversion procedure was introduced converting the weights into probabilities.

Global Methods

- **Random Walk with Restart (RWR).** [Kohler et al. \(2008\)](#) proposed the random walk analysis for definition of similarity in PPI networks demonstrating that global network-similarity measures (random walk and diffusion kernel) are greatly superior to local distance measures (direct links or shortest paths) in the disease-genes prioritization problem. They performed a random walk on the PPI network, starting at the known disease genes, and rank candidate genes by the steady state probabilities induced by the walk. In the RWR procedure, a random walk starts at one node in the set S of known disease genes (seed genes): the random walker can move to a randomly selected neighbor or it can restart at one of the proteins in S . For each restart, the probability of restarting at a specific protein is r . Formally, RWR is defined as:

$$p^{t+1} = (1 - r)Wp^t + rp^0 \quad (4)$$

where W is the column-normalized adjacency matrix of the graph and p^t is a vector of probability of being at node i at time step t . In Kohler *et al.* (2008), the authors set the initial probability vector p_0 with equal probabilities to the nodes of S , with the sum of the probabilities equal to 1 (disease genes with equal probability).

- **PRINCE (PRIoritizationN and Complex Elucidation)**. To compute the association between disease genes and candidate proteins, Vanunu *et al.* (2010) proposed a network propagation algorithm based on formulating constraints on the prioritization function that relate to its smoothness over the network and usage of prior information. PRINCE receives as input a disease-disease similarity measure and a network of protein-protein interactions. The algorithm infers a strength-of-association scoring function that models an information pump that originates at the seed sets: this function is smooth over the network (adjacent nodes are assigned with similar values) and respects the prior knowledge on causal genes for the same disease or similar ones.
- **DA DA**. In Erten *et al.* (2011), the authors proposed DA DA (Degree-Aware Algorithms for Network-Based Disease Gene Prioritization), a free available suite implemented in Matlab. This algorithm applies statistical adjustment methods to correct for degree bias in information flow based disease gene prioritization with the aim to limit the prediction errors due to the incompleteness and the noisy network of PPI networks. Despite methods based on random walks or network propagation as the two above described (Kohler *et al.*, V1.36., 2008; Vanunu *et al.* 2010), are less affected by this problem by considering multiple alternate paths and whole topology of PPI networks, DADA outperforms these methods.
- **ProDiGe**. The algorithm proposed in Mordelet and Vert (2011) implements a novel machine learning strategy based on learning from positive and unlabeled examples: it assumes that a set of gene-disease associations is already known to infer new ones. The main difference from the existing approaches, is the definition of a scoring function using both the set P of known disease genes (positive examples) and the set U of candidate genes (unlabeled examples), formulating the problem of disease genes prediction as an instance of the problem known as learning from positive and unlabeled examples (PU learning). Moreover, ProDiGe is characterized by other two properties: i) it exploits information about known disease genes across diseases; ii) it allows heterogeneous data integration (sequence features, expression levels in different conditions...).
- **DIAMOnD (DIseAse MOdule Detection)**. In Chiassian *et al.* (2015), the authors showed that disease associated proteins do not reside within locally dense communities and that connectivity significance is the most predictive quantity. Based on these results, they developed a novel algorithm (DIAMOnD) that performs a systematic analysis of the network properties exploiting the connectivity significance instead of connection density. To identify disease modules, DIAMOnD algorithm performs the following steps:
 - i. computation of the connectivity significance for all proteins with at least one connection to any of the seed proteins:

$$p\text{-value}(k, k_s) = \sum_{k_i=k_s}^k p(k, k_i) \quad (5)$$

where s_0 is the relatively small number of seed proteins associated with a particular disease and $p(k, k_s)$ is the probability that a protein with k links has exactly k_s ($k_s < k$) links to seed proteins given by the hypergeometric distribution:

$$p(k, k_s) = \frac{\binom{s_0}{k_s} \binom{N-s_0}{k-k_s}}{\binom{N}{k}} \quad (6)$$

where N is the number of proteins;

- ii. ranking of the protein according to their respective p-values;
- iii. the protein with the highest rank (i.e. lowest p-value) is added to the set of seed nodes, increasing their number;
- iv. steps (i)-(iii) are iterated with the expanded set of seed proteins, pulling in one protein at a time into the growing disease module.

The procedure (i)-(iv) can be continued until the entire network is agglomerated. The order in which the proteins are being pulled in to the module reflects their topological relevance to the disease, resulting in a ranking of all proteins.

Conclusion and Perspectives

Among the obstacles and future perspectives concerning network inference, the discovery of ‘actual’ causal regulatory networks in the gargantuan space of possible networks is among the most formidable ones, just considering that the number of possible arrangements, i.e. different networks, of a relatively ‘trivial’ gene regulatory network containing as little as 50 nodes outclasses the estimated number of atoms of the observable universe ($\sim 10^{80}$). In such a challenge, it can be easily anticipated that previous knowledge, in terms of background, exploitable information, including already extracted causal connections and subnetworks, will likely impact the quality and quantity of successive attempts (or network ‘updates’) of network reconstruction in the different fields. Optimization methods, algorithmic progresses, innovative analytics and well-founded statistical inference as well as efficient approaches for integrating omic data and information will drive advancements in network reconstruction that should eventually speed up biological discovery, by helping in the avoidance of inaccurate or far from optimal network configurations.

Lately, artificial neural networks -deep learning- approaches are receiving more attention and resources in computational biology, thanks to their ability to capitalize on the accessibility and convenience of high-throughput omic data: better performance and higher-level characteristics can be obtained over conventional modelling methodology, and they could potentially deliver crucial understanding about the organization of biological networks.

The last decade has witnessed the relentless growth of biological molecular data (the so-called “omics” revolution) driven by highly efficient biotechnological devices and methods. Also, neuroscientists recently started collecting multi-subject, multi-modal human neuroimaging datasets: speaking more in general, ‘big data’ is the new reality also in biology, medicine and neuroscience. This growth is still ongoing and even increasing in speed and quality of outcomes. However, despite initial enthusiasms, the challenge of its management and use for the understanding of diseases has become over time a daunting task. In other words, the goal of turning lead into gold, i.e. transform data into knowledge, seems to step far away every single day. As a matter of fact, experimental measurements on almost every molecular entity acting in a cell are now currently available on databases spread all over the world, and this “heap” of data is incredibly huge and ever-increasing. The inevitable consequence of such wild expansion is that now it is practically impossible to put all the pieces together for two basic, simple reasons: (1) there are many missing ones, and (2) they are virtually infinite, so that the current ‘data factory’ is unlikely to stop working or even slow down. Now, it is time for asking questions and provide frameworks for real inter-disciplinary studies.

Network representations are invaluable for this purpose, as just shown. A network is the ideal metaphor for representing relationships among data, finding “patterns” for biomarker studies and, most importantly, any kind of expertise can find the opportunity to fully express itself using a common language. In fact, the network metaphor provides plenty of words and concepts that can be exploited by biologists and clinicians to represent their knowledge, and by bioinformaticians or computational modellers to derive algorithms and find answers using computation and mathematics. In other words, we envisage a new way of conceiving a “inter-disciplinary team” where biology and computation can flourish together (Korcsmaros *et al.*, 2017). The key point is that researchers should leave behind grand visions of “universal principles” and start an “earthly” work of untangling one by one the long list of problems that ask for (at least partial) answers in a peer-to-peer inter-disciplinary setting where the network metaphor provides the language to go beyond the conceptual/computational barriers.

Introduction

Large-scale biological networks are being generated at a growing rate. Advances in experimental biotechnologies are yielding molecular interaction networks of various types, including protein-protein interaction (PPI), epistatic genetic interaction (GI), metabolic reaction, and transcriptional regulation data, among others (Snider *et al.*, 2015). As each data set in isolation carries only limited information about biology and as the data sets complement each other (Przulj and Malod-Dognin, 2016), extracting new biological information hidden in the wiring patterns of these complex interconnected “big data” has received much attention in the scientific community and industry. These data are often modelled as *networks* (also called *graphs*), in which biomolecules are modelled as *nodes* (also called *vertices*) and their interactions are modelled as *edges* (also called *links*). Hence, biological systems have been modelled and analysed by using networks (Barabasi and Oltavi, 2004).

However, analysing large networks is mostly computationally intractable. Computational complexity theory studies hardness of computational problems and many of the problems underlying analytics of large networked data fall into the category of computationally intractable problems, so called NP-hard and NP-complete problems (Bondy and Murty, 1976). In short, computational problems roughly fall into the two main categories: polynomial time solvable problems (P) and non-deterministic polynomial time hard (NP-hard). Class P contains problems for which we can compute exact solutions in the time that is polynomial of the size of the input data. These problems are called computationally *easy*. In contrast, NP-hard problems cannot be solved exactly on large scale data, so we must solve them approximately, or heuristically. Some intractable problems include network comparison and alignment, which are hard due to NP-completeness (special type of NP-hard problems) of the underlying sub-graph isomorphism problem (Cook, 1971).

Proteins are key to the functioning of the cell and hence PPI networks play important roles in the functioning of cells. Similarities in the wiring of proteins within a PPI network have been shown to also mean similarity in biological function. Similarities in wiring patterns of proteins in PPI networks can also be used to guide network alignment algorithms, which analogous to sequence alignments, find and align similarly wired and similarly functioning proteins over PPI networks of different species. This, in turn, is used to transfer annotation from model organisms to human. Network motifs and graphlets have been used to address all these issues.

Network Motifs and Graphlets

For the above reasons, many approximate methods to analyse the structure of biological networks have been proposed. They can roughly and historically be divided into *local* and *global network properties*. Simple examples include the *degree* of a node (the number of edges that the node participates in), the *degree distribution* (the distribution of degrees over all nodes of a network), the *clustering coefficient* of a node (the number of edges between the neighbours of a node as a percentage of the maximum possible number of edges between them), the *average clustering coefficient* of the network over all its nodes etc. (Newman, 2010). More detailed descriptors of network structure include methods based on *network motifs* and *graphlets*, which are the subject of this article.

Network Motifs

Network motifs have been introduced by the group of Uri Alon (Milo *et al.*, 2002). They are defined as small patterns of interconnections occurring in complex networks at numbers that are significantly higher than those in randomized networks (Milo *et al.*, 2002). They were used to study the transcriptional regulation networks of well-studied microorganisms (Alon and Mangan, 2003; Mangan *et al.*, 2003), as well as of higher order organisms (Charney *et al.*, 2017; Datta *et al.*, 2017). It was shown that these networks appear to be made up of a small set of recurring regulation patterns, captured by network motifs.

Example motifs include positive and negative autoregulation, positive and negative cascades, positive and negative feedback loops, feedforward loops (FFLs), single input modules, and combinations of these, illustrated in Fig. 1 (Shoval and Alon, 2010). They were linked with biological function (illustrated in Fig. 1). Since the same network motifs have been found in diverse organisms from bacteria to humans, it has been suggested that they serve as basic building blocks of transcription networks. Network motifs in other biological networks also seem to exist, including signalling (Ptacek *et al.*, 2005; Itzkovitz *et al.*, 2005; Ma'ayan *et al.*, 2005) and neuronal networks (Sporns and Kotter, 2004; Sakata *et al.*, 2005). Also, they were used to analyse integrated networks of transcriptional regulation and protein-protein interactions (Yeger-Lotem *et al.*, 2004). For a review, see Alon (2007).

“Temporal motifs” were introduced to study the temporal changes in local network structure over time-evolving networks. For example, static network motifs described above were counted in each network snapshot over time and then their counts compared across the snapshots (Braha and Bar-Yam, 2009). This approach ignored any motif relationships between different network

Fig. 1 An illustration of different types of network motifs and their functions. Taken from Shoval, O., Alon, U. 2010. SnapShot: Network motifs. Cell 143, 326.

snapshots. Hence, static network motifs were extended into several notions of temporal motifs (Chechik et al., 2008; Kovanen et al., 2011). Intuitively, temporal motifs are classes of sequences of similar network event sequences, where the similarity refers both to topology and to the temporal order of the events.

To understand the difference in the definition of motifs and graphlets, we need to introduce the following simple graph theoretic terms. A *partial subgraph* is a subgraph of a larger network in which once we pick the nodes that form the subgraph, we can pick any subset of edges between the chosen nodes of the larger network. An *induced subgraph* is a subgraph in which we must pick all the edges between the chosen nodes of the larger network to form the subgraph. Both of these subgraph definitions are illustrated in Fig. 2. Network motifs are partial subgraphs that are significantly overrepresented in the data compared to a chosen random graph model that is assumed to fit well the data.

However, as network comparison is computational intractable, determining a well-fitting network model is hard, as it involves comparing the data network with model networks. A random network model that is usually used as well-fitting is that of a random graph constructed to have the same degree distribution as the data network, while edges are drawn at random. Also, note that motifs are partial subgraphs, while characterizing the structure of any graph class is based on induced subgraphs (Andreas Brandstädt, 1999). An anti-motif is defined similar to a network motif, but it needs to be under-represented in the data compared to a random network model.

Hence, analyses of biological networks involving network motifs have been criticised, since the definitions of motifs and anti-motifs heavily depend on the choice of a random graph (network) model (Artzy-Randrap et al., 2004; Milo et al., 2004), since they are partial subgraphs (Przulj et al., 2004) and since they can exhibit a whole range of dynamic behaviours (Ingram et al., 2006). Furthermore, it is computationally hard to identify network motifs (and the same holds for graphlets), as the number of possible sub-graphs increases exponentially with the network and motif size (node and edge counts). Hence, various algorithms for their

Fig. 2 Partial vs induced subgraphs. In the fully connected network with 3 nodes illustrated in panel A, if we pick all 3 of its nodes to make connected subgraphs, there exist three partial subgraphs corresponding to 3-node paths, illustrated in panels B, C and D, but only one induced subgraph, a triangle, illustrated in panel E.

Fig. 3 All 2- to 5-node graphlets, \$G_0\$ to \$G_{29}\$, along with their symmetry groups (automorphism orbits), numbered from 0 to 72. Taken from Przulj, N., 2006. Biological Network Comparision Using Graphlet Degree. Oxford University Press, pp. e177–e183.

detection have been proposed, including those involving parallel and cloud computing (Kim *et al.*, 2013). A survey paper from 2011 discusses the biological significance of network motifs, the motivation for finding them, as well as the strategies for solving various aspects of this problem (Wong *et al.*, 2011).

Graphlets

As a response to the above mentioned drawbacks in the definition of network motifs, *graphlets* were introduced (Przulj *et al.*, 2004). Graphlets are small, connected, induced subgraphs of large networks (Przulj *et al.*, 2004). They can appear in the data network at any frequency and hence their definition does not depend on any assumed random graph model that fits well the data. Also, they are induced, so they are a suitable tool for designing various algorithms for mining domain relevant new information from the structures (topologies) of biological and other network data. All 2- to 5-node undirected graphlets are illustrated in Fig. 3.

As systems-level molecular network data present an opportunity to discover new biological information, several data analytics algorithms included graphlets as the underlying methodology aimed at uncovering the additional meaning. For instance, *graphlet frequency distribution* is introduced to be superior to the *degree distribution* (which is the first in the spectrum of 73 graphlet degree distributions), the *clustering coefficient* (the measure of “cliquishness” of the network) and *network diameter* (which measures how “far spread” the nodes of the network are) by imposing a large number of similarity constraints on the networks being compared (Przulj, 2006). It does so by generalizing the degree distribution (which measures the number of nodes touching k edges) into a spectrum of 73 distributions measuring the number of nodes touching k graphlets at a particular orbit for each value of k (the 73 orbits for 2- to 5-node graphlets are numbered in Fig. 3). Basically, it compares sequences of numbers over 73 pairs to compare two networks. It can be classified into both types of network comparison heuristics, global and local, as it does comparison globally over the entire network, but uses local network features in the comparisons.

As biological networks are globally incomplete, but locally more complete (due to biases in biotechnologies and experimental design focusing on heavily exploring the parts of networks relevant for human disease), focusing more on local network properties provides a better measure of network structure for these particular data (Przulj, 2006). This was demonstrated on 14 real PPI networks and the four network models (Przulj, 2006). Also, it was shown for the first time that *geometric random graphs* are fitting PPI networks better than other previously used models (Przulj *et al.*, 2004). In geometric random graphs, nodes correspond to points randomly distributed in a metric space and edges are drawn between the points if the corresponding points are close

enough (within a given radius) in space. This model was later refined to mimic network growth inspired by gene duplication and mutation events (Przulj *et al.*, 2010).

A more sophisticated heuristic measure of distance between networks is called *Graphlet Correlation Distance (GCD)*, which exploits correlations between graphlet orbits (symmetries in graphlets, see Fig. 3) over all nodes in a network, to compress the topology of a network of any size and density into an 11 by 11 matrix of numbers between -1 and 1 , the so called Graphlet Correlation Matrix (GCM). It compares GCMs of different networks to find the topological similarity between the networks (Yaveroglu *et al.*, 2014). The superiority of GCD over other measures was demonstrated not only in accuracy, but also in noise tolerance and computational efficiency (Yaveroglu *et al.*, 2015). GCD demonstrated relationships between unrelated networks, such as, Facebook, metabolic, and protein structure networks. Biological networks were also compared by the method involving differential graphlet communities (Wong *et al.*, 2015).

The constant production of large scale, dynamic and directed correlated data has demanded development of more sophisticated methods to analyse them and gain additional biological insights. Analysing directed networks by using graphlets was proposed, since their above described undirected counterparts were successful in analysing undirected network data. Graphlets and their degrees were extended to directed data, as well as the GCD measure (Sarajlic *et al.*, 2016). It was demonstrated that these directed versions of graphlet-based tools are more sensitive in comparing directed networks than if the undirected version was applied to directed data. Additionally, it was necessary to extend the conical correlation analysis framework to facilitate uncovering the relationships between directed network wirings and their annotations. The method was applied to metabolic networks (Sarajlic *et al.*, 2016).

Algorithms for Graphlet Identification

However, identifying graphlets is computationally demanding as one needs to search through exponentially many possible subgraphs, so heuristic approaches have been sought (Przulj *et al.*, 2006; Wang, *et al.*, 2016). For instance, by using geometric graphs as a well-fitting model of PPI networks, a heuristic exploits the property of geometric graphs being sparser at the “boundary” and denser in the “core” of the network to quickly estimate graphlet counts in geometric graphs and also in PPI networks, since they are fit well by geometric graphs. This heuristic is called Targeted Node Processing (TNP), since it targets counting of graphlets in these sparse, network boundary neighbourhoods and from them estimates the counts in the entire network. The same paper proposes another heuristic called Neighbourhood Local Search (NLS) that is based on a more standard sampling search procedure of randomly sampling nodes and counting graphlets around them to produce the estimates (Przulj *et al.*, 2006). Both heuristics work well for high-confidence PPI networks, which have power-law degree distribution, as well as for geometric random graphs which do not, indicating that the behaviour of the heuristics is dictated by the local rather than global structure of these networks. A combinatorial method was also proposed, using a system of equations that connect counts of orbits in graphlets to allow for computing of all orbit counts by enumerating a single one, hence reducing practical time complexity in sparse graphs by an order of magnitude compared to the exhaustive enumeration-based algorithms (Hocavar and Demsar, 2014).

Graphlets Link Network Structure and Biological Function

Since few protein structures have been resolved, predicting structure and function of uncharacterized proteins has been attempted by using various data sets. The traditional techniques were based on homology, but with the availability of systems-level PPI data that aim to capture the entire proteome, the questions arose of whether protein function could also be predicted from PPI network data. In this direction, a graphlet-based method demonstrated that the local structure around a protein in a PPI network and its biological function are related (Milenkovic and Przulj, 2008). The method uses a vector of graphlet degrees, called a *signature* of the protein in the PPI network, and computes the similarities of signatures of proteins across all protein pairs. It demonstrated that when the local wiring patterns around proteins are similar and proteins are grouped based on these similarities, the grouped proteins tend to perform the same biological functions, belong to the same subcellular compartments and have the same tissue expression. These observations opened up research directions for experimental design and for disease protein prediction from proteome-scale network data.

Also, new disease genes were identified from the analysis of the topology of PPI networks. It was assumed that neighbours of disease genes in the PPI network are also involved in the same or similar diseases (Ideker and Sharan, 2008). Simple network properties of disease genes were used in order to identify new gene-disease, or drug to drug-target associations. For instance, it has been demonstrated that cancer genes have larger connectivities and centralities compared with non-cancer genes (Jonsson and Bates, 2006). However, the relationship between disease genes and their network degree (number of neighbours they have in the network) needed to be analysed in more detail, because many diseases genes code for proteins that are not hubs in PPI networks (Goh *et al.*, 2007). Hence, demonstrating a relationship between cancer genes and their wirings in the PPI network required more sophisticated methodology.

Since it has been demonstrated that proteins with similar wirings in PPI networks can have the same functions (Milenkovic and Przulj, 2008), the new challenge was to establish if cancer genes also exhibit similarity of their topological graphlet degree signatures. Indeed, when signatures were used to predict new cancer genes purely from the topology of PPI networks, 80% of the predicted new cancer genes were validated in the literature (Milenkovic *et al.*, 2009). Furthermore, the biological validations with siRNA screens confirmed some of the predictions, in particular cancer-related negative regulators of melanogenesis (Milenkovic

et al., 2009). The results were more encouraging than expected, as the predictions were obtained only from PPI network topology, demonstrating their importance as a source of new biological information. Also, the study showed evidence that the structure of the PPI network around cancer genes is different from the structure around non-cancer genes.

Furthermore, graphlets were used to show that similarity of wiring of proteins and the link of their wiring with biological function is conserved over species even as distant as yeast and human (Davis *et al.*, 2014). It was noted that the variability of topology-function relationships required more investigation to make functional predictions and do annotation transfers, because the topology-function relationship may differ between different species and between different protein functions. To address this issue, a statistical framework was built by using conical correlation analysis (CCA). In this direction, the wirings around proteins in a PPI network are represented by graphlet degree vectors and correlated with Gene Ontology (GO) annotations (Ashburner *et al.*, 2000) by using CCA. As a result, statistically significant topology-function relationships were obtained between yeast and human. Functions that have conserved topology in PPI networks of these species were discovered, which were called “topologically orthologous” functions (Davis *et al.*, 2014).

A question of how much functional information could be obtained from sequence and how much from PPI network topology, and whether the two data types as sources of biological information corroborate, or complement each other has also been addressed by using graphlets (Memisevic *et al.*, 2010). Complementarity of PPI network and sequence information in homologous proteins has been examined, as PPI network topology and protein sequence may provide details into different slices of biological information (Memisevic *et al.*, 2010). The goal was to ensure that no biological information is lost by considering only sequence as a relevant source of biological information. First, it was examined if the information about homologues captured by the PPI network topology by using graphlet degree vectors (signatures) differs and to what extent from the information captured by their sequences. The similarity of topology around homologous proteins in the PPI network was statistically significantly higher than in non-homologous proteins. Second, none of the data sources, network topology and sequence, seemed to capture homology information entirely. However, it was demonstrated that both data sources provide relevant and complementary functional information, concluding that topological neighbourhoods of a protein in the PPI network could complement sequence-based information to identify homologous proteins.

Graphlets were used to analyse other biological networks as well. In a brain functional network, brain regions are modelled as nodes and if they are simultaneously active while the brain performs a cognitive task as measured by electrocorticographic signals, then the corresponding nodes are linked by an edge. It was established that these brain connectivity networks have a small-world topology (Basset and Bullmore, 2006). However, novel graph theoretic techniques analysed brain function networks to allow us to identify structural changes in the brain's wiring as a result various stimuli, or cognitive tasks. On brain functional networks of six epileptic patients, by using graphlet-based network similarity measures, it was found that during resting, these networks are differently wired than during performing cognitive tasks (Kuchaiev *et al.*, 2009).

In addition, analysing temporal real-world networks is a challenge. There are various options on how to model a temporal network, for example, as single aggregate statistic networks, or as a series of time-specific snapshots. Depending on the modelling, there can exist limitations in extracting information from them, because valuable temporal information could be lost if a static analysis is implemented. They were studied by considering evolution of their global network properties (Leskovec *et al.*, 2005; Nicosia *et al.*, 2012). Also, graphlets were used to study temporal networks by registering intermediate snapshot relationships (Hulovatyy *et al.*, 2015). This use of graphlets was proposed as an alternative to the one based on temporal motifs described above to alleviate the above noted limitations of finding the well-fitting null model that's required to define motifs, which is a complex task. This method was applied to age-specific molecular networks to better understand the processes of human aging.

Graphlets in Network Aligners

Another bioinformatics application in which graphlets are used is that of network alignment. Just as sequence alignment algorithms have revolutionized our understanding of biology, aligning systems-scale molecular networks will have similar ground-breaking impacts. However, as described above, aligning networks is computationally intractable due to NP-completeness of the underlying subgraph isomorphism problem. Hence, heuristic algorithms for network alignment have been proposed (Kelley *et al.*, 2004). One of the first algorithms to use purely network topology without sequence to align pairs of PPI networks is based on a seed-and-extend approach where nodes with the most similar graphlet-based topological signatures in the PPI network are aligned and then the alignment was extended around these seed nodes in a principled way (Kuchaiev *et al.*, 2010). It was applied to biological networks to produce the most comprehensive network alignments at the time, exposing surprisingly large regions of PPI network topological similarity even in species as distant as yeast and human. It produced new insight into phylogeny and biological function. As there are many possible alignments, the question of which one is optimal was addressed by using the Hungarian algorithm for solving the bipartite matching problem, where the bipartitions are nodes (proteins) of PPI network being aligned (e.g., yeast and human) and the edges across represent graphlet degree vector similarity scores between the nodes (Milenkovic *et al.*, 2010). The latest in the series of graphlet-based aligners is L-GRAAL, which combines the statistics of graphlets with Lagrangian relaxation to produce the state-of-the-art alignments (Malod-Dognin and Przulj, 2015).

Another application of graphlets-based network aligners is in structural biology. Alignments of protein structures aim to deliver the most accurate mappings of equivalent residues and elucidate protein function. Aligning protein structures has attracted considerable research efforts, since there is no algorithm that yields satisfactory results and since the existing algorithms are not

applicable to large scale data. Hence, proteins have been modelled as networks, in which nodes are residues and an edge exists if the corresponding residues are close enough, usually within 5 Å. As graphlets were used to design sensitive topological similarity measures between nodes and networks, the question was whether they could also be used to align protein structures. A method called GR-align was introduced for alignment of protein structures, which uses a maximum Contact Map Overlap (CMO) that is suitable for database searches (Malod-Dognin and Przulj, 2014). GR-align is more efficient in terms of speed than other similar methods. Additionally, its similarity scores agree with the structural classification of proteins. The method was applied on the Astral-40 dataset. Apart from producing better scoring than other structure alignment heuristics, it also produced results with higher level of agreement with the structural classifications proteins. GR-align also allowed for transferring more information across proteins (Malod-Dognin and Przulj, 2014).

Despite these efforts, aligning pairs of large networks still represents a challenge. Aligning multiple networks is even more challenging, as performance of such aligners decreases with increase in the number of networks being aligned. Another challenge to be met by a multiple network aligner is to deliver clusters of nodes (genes) that are evolutionarily and functionally conserved across all aligned networks, i.e., to produce both topologically and biologically meaningful alignments. The current state-of-the-art multiple network alignment algorithm, called Fuse, works in two steps (Gligorijevic *et al.*, 2015). First, it generates node (protein) similarity scores across multiple PPI networks by using penalized (graph-regularized) non-negative matrix tri-factorization (NMTF) for fusing information from wiring patterns of all aligned protein-protein interaction (PPI) networks and sequences similarities between their proteins. Second, it identifies clusters of aligned proteins over all networks, for which it proposes a new heuristic for addressing an NP-hard problem of k-partite matching for $k > 2$. Fuse outperforms others aligners and produces a larger number of biologically consistent clusters that cover all aligned protein-protein interaction (PPI) networks.

Concluding Remarks

Despite significant advances in methods based on network motifs and graphlets for analysing and extracting new biological and medial information from large-scale molecular networks, we are far from comprehensively understanding biological systems such as cells, tissues, or organs. Roles of molecular networks in health and disease are still to be uncovered and once uncovered, they need to be altered by therapeutics to improve patient treatment and care. Each individual network type gives insight only into one slice of biological information. Graphlet- and motif-based methods need to be complemented by new sophisticated graph theoretic methods capable of capturing multi-scale organization of biological systems. Furthermore, these new methods and formalisms need to be integrated within data fusion frameworks, so that we would get a data-driven, full understanding of a biological system by mining all available data collectively.

Biographical Sketch

Laurentino Quoroga Moreno is a Colombian engineer. He moved from his home country to the UK in 2007 to study English and enrol into post-graduate studies at King's College London supported by a scholarship from Colombia. In 2012, he obtained a postgraduate certificate in Engineering with Business Management from King's College London. He worked in private and public sectors for many years. In 2016, he changed disciplines and entered an MSc program in Bioinformatics with Systems Biology at Birkbeck College, University of London. Currently, he is carrying out his research project at University College London in the department of Computer Science on disease-disease relationships from systems-level molecular network data.

Introduction

Biological Interaction

Proteins are organic macromolecules which have the ability to act together with several other molecules, including other protein (Moraes, 2013). They are normally identified by their individual actions as catalysts for reactions in metabolic pathways, signaling molecules in intracellular regulation cascade, defense proteins such as antibodies, nutrient or storage proteins, motile or contractile proteins (Jeong *et al.*, 2001; Phizicky and Fields, 1995). But the proteins are also identified by structural actions carried out by the interaction by forming complexes such as proteins of the cytoskeleton, signal transduction, cell-to-cell communication, transcription, replication and membrane transport (Keskin *et al.*, 2016). Regardless of the activities to be structural, metabolic or regulatory, proteins are important in maintaining homeostasis of the organism through the interactions that form each other and with other molecules, are essential for any living organism.

For some proteins become active and perform its function, it is required that binds to other molecules, thus forming monomers, dimers, trimers, polymers, etc. A monomer is defined as a molecule capable of binding to other molecules. When two monomers (molecules/proteins) are bound are called dimers, and if the dimer is formed by the same protein is called homodimers. A dimer sample can be observed with a binder in the structure of thymidylate synthase (TS) (PDB: 5X69), an enzyme of the transferase class with function to catalyze the synthesis monophosphate thymidine (dTMP) from uridine monophosphate (dUMP), essential in DNA synthesis and directly linked to tumor proliferation rate (Chen *et al.*, 2017). Trimers are joints of three monomers, for example the Dynamic HIV Envelope Trimer Apex complexed with neutralizing HIV antibodies (PDB: 5V8L) (Lee *et al.*, 2017) and when it is formed by the junction of the same molecules is termed homotrimer. The polymers contain a large number of monomers linked such as retinal protein for cell-cell adhesion (retinoschisina – RS1) an octamer consisting of eight monomers (PDB: 3JD6). When they are composed of the same molecule form a homopolymer such as the Ebola virus membrane-associated matrix protein (vP40) formed by four antiparallel homodimers (PDB: 1H2D).

The biological interactions maintain proper functioning of the body and occur at all times to ensure the production or non-production of biomolecules involved in metabolism. Proteins are key elements in the interactions processes and they are responsible for modulating catabolism and anabolism processes with synthesis or degradation of essential molecules, respectively.

The biological interactions can be defined as a mutual operation of several components of an organism to ensure proper sequence of events that together ensure the development of the individual. With the premise that all living beings have evolved from a common ancestor we can assume that, in addition to genes and proteins, the interactions are conserved.

The biological interactions occur only within a single organism or cell, they also occur between different host-pathogen interactions of bacteria *Mycobacterium tuberculosis* and Homo sapiens and the knowledge of this protein-protein interaction network (PIN) is an important tool for understanding how the bacteria interact with their host and expresses its virulence (Huo *et al.*, 2015). The knowledge about the proteins and how they interacts in a PIN enables a systemic understanding of the organism, cell or metabolic pathway, and may able since the discovery of new therapies to treat diseases until the knowledge about the metabolism of the microorganisms to be used in industrial, pharmacological, agricultural or livestock bioprocesses. Estimates indicate on average 30% of the organisms' proteins are identified in the interaction networks, with PINs being a large area of study and with many possibilities still open (Hao *et al.*, 2016).

For an interaction to exist, it is necessary to have a fine space-time coordination, that is, both partner proteins must coexist in the same cellular location at the same time (Hao *et al.*, 2016). This leads to the thought that for an interaction to occur, it is not enough just to have the respective coding genes, the proteins need to be transcribed and translated at the same time and in the same place. This fact has an even greater relevance in eukaryotic, because at least the interacting proteins must be expressed or transported to the same tissue. In time, transmembrane or secreted proteins are able to interact with proteins outside the cell environment such as occurs in the host-pathogen interactions. These characteristics exert direct influence on the methods of identification and prediction of interaction and, if not considered, can lead to false positive or false negative identification.

In order to understand a PIN is necessary to know the types and characteristics of each protein interaction.

Interactions Types

Interactions between proteins can be classified as physical (structural) or functional (regulatory). An interaction is physical when there is physical contact between two proteins and it is functional when there is an activation or inhibition event between the biomolecules, often mediated by intermediary cellular processes as in a metabolic pathway.

Interactions may also be classified according to duration time as transient or persistent. The transient interactions occur for a short period of time when a protein binds to the other only at a time and, after performing its function are separated. Persistent interactions tend to be more stable and occur when proteins remain bound for a longer period or until they are degraded (Nooren and Thornton, 2003). In time, the proteins may be classified according to the amount of interaction. Proteins with many interactions are termed hubs and play a central role in PIN by connecting several other proteins, probably assuming several functions and participating in several metabolic pathways.

These types of interactions are not exclusive and may occur simultaneously. Due to the temporary nature, transient interactions are more difficult to identify and study. Physical interactions are important targets in the development of a new class of drugs with the potential to inhibit or stabilize interactions.

Interaction Representation

The representation for PINs view is based on graph theory, coming from the exact area. An interaction is symbolized by nodes (representing proteins) and by vertices linking these nodes (representing the interaction), as can be observed in Fig. 1.

In biological networks, typically the interactions are non-directional, indicating there is no source or destination for interaction and can be stated without loss of information that both the protein 'A' interacts with the protein 'B' as protein 'B' interacts with 'A'.

A directional interaction is represented by an arrow ($>$) at the end of vertex indicating the direction of interaction, thus having source and destination in the proteins of the interaction. Two proteins form an interaction, and several interactions, peer-to-peer, form a complex Protein Interaction Network (PIN), which may contain hundreds or thousands of interactions.

Protein-Protein Interaction Network (PIN)

The PINs, also known as interactome, are important tools for the systemic study of an organism, since they represent a set of protein interactions whose characteristics are susceptible of analyzes inherited from the graph theory. It is possible to observe in a PIN, since interactions between proteins in a complex or in a metabolic pathway until a set of pathways, comprising both organisms showing low complexity as those with high complexity (Szklarczyk *et al.*, 2011). By analyzing the characteristics, a PIN provides elements for a great variety of studies, such as (i) understanding the organism studied at a systemic level, (ii) visualizing and complementing metabolic pathways, (iii) presuming protein functions and assisting the annotation process of genes and hypothetical proteins, (iv) identify new targets for drugs and (v) suggest new therapies to treat diseases (Pavlopoulos *et al.*, 2011).

Biological Network Characteristics

A PIN such as the World Wide Web, as Facebook ® or personal network is a biological network. The biological networks in general, whether of people or proteins, present similar characteristics but different from non-biological networks. Using analysis of graph theory these characteristics can be identified and applied for a better understanding of the network aiming at biological purposes.

Degree: is a measure that indicates the number of edges possess a node. In PIN is a particular characteristic of each protein, indicates with how many other proteins a protein interacts. It is a feature that generally can change the topology of a PIN and have important biological applications. A protein that has a high degree of interaction, which interacts with many other proteins, is called a *hub*. The hub proteins by interacting with many proteins form large tightly connected groups and tend to participate in several metabolic pathways or biological processes, assuming diverse functions.

The hub proteins have important cellular function, indicating that if they are removed from the PIN, the organism may not perform its basic functions, justified by the disruption that the removal of a hub node causes in the network, probably affecting several metabolic pathways (Pavlopoulos *et al.*, 2011; Jeong *et al.*, 2001). *In silico* studies suggest that the hub proteins are under high evolutionary pressure, because (i) they are more conserved among organisms, (ii) they have a lower mutation rate in their sequences, they also have a conserved evolution, and (iii) they are correlated with proteins essential (Dilucca *et al.*, 2017). Just because they are conserved and under selective pressure, it indicates the hub proteins have some singular significance for the organisms.

However, how many interactions a protein must have to be considered a hub? This answer is not given in absolute numbers because the amount of interactions identified in a PIN is dependent on the methodology used, ie in the same organism, different

Fig. 1 Nodes represent the proteins (A and B) and the vertex is the interaction between the nodes.

methodologies identify amount of different proteins and interactions. This is a problem even to replicate or validate experiments. For this reason the hub proteins are sorted by relative values, such as 15% (Folador *et al.*, 2016) or 20% (Delprato, 2012) of the protein with a higher degree of interaction in the PIN. There is no consensus on the exact value to define hub proteins and the choice of one or another value depends on how much you want the identification is more or less sensitive.

When a hub protein interacts with its partner proteins simultaneously it is named the Party hub. Party hub generally interact physically with their partners and form complexes performing distinct function, such as proteins composing polymers or homo-polymers. Complementarily, a protein hub that interacts with different partners at different time or place is named date hub. Date hubs are proteins that participate in functional interactions, usually assuming role of regulation in signaling cascades or participating enzymatically in the stages of different metabolic pathways (Hao *et al.*, 2016).

The interactions around hub proteins influence the topology of a PIN and can form two network models, assortative or dissortative. When hub proteins are more connected to other hub proteins, the network is named assortative and, contrary, when connecting to proteins having low interaction degree is named dissortative (Pavlopoulos *et al.*, 2011). Usually biological networks are dissortatives with hub proteins interacting more with proteins having low interaction degree than protein hub (Newman, 2003). These features contribute to the specificity of biological networks and differentiation from non-biological or random networks, and may used as a first layer to in-silico validation by analysis of the interaction degree distribution for PPIs.

Scale-free distribution: It is a topological measure of interaction networks. Biological networks have a scale-free distribution to interaction degree of each node with tendency to power-law (Fig. 2 left), different from random networks showing normal distribution (Fig. 2 right).

The PIN having a scale-free distribution indicate has a large number of proteins with few interactions and a small number of proteins with a large number of interactions (Barabási and Albert, 1999). This fact is in agreement with the presence of hub proteins in PPI concentrating most interactions while other proteins have few interactions. This characteristic indicates biological interactions do not occur randomly or by chance, reinforcing the evolutionary pressure occurs in the interactions, evidencing the importance of precise interactions in the maintenance of life.

Small-world-effect: It is a topological measure of interaction networks. The effect of small world (or shortest path) indicates that any two nodes are separated by only a few edges (Barabasi and Oltvai, 2004), this explains for example that anyone in the world is connected to another on average by 5 or 6 people. In biological networks, this means that the disturbance of any protein will propagate in the network because a few proteins separate all other proteins, suggesting the interactions within a cell are closely related. Certainly, hub proteins contribute for this effect by keeping a strongly connected PIN, reducing the distance between the proteins. Without the hub nodes, the distance between all proteins would probably the same indicating both paths and random network.

Clustering coefficient: in graph theory, is a measure indicating how much the nodes tend to cluster in a network (Pavlopoulos *et al.*, 2011). Clusters are densely interconnected sets of nodes and vertices and the clustering coefficient is used as a feature of biological networks. Generally, PINs present a high clustering coefficient in relation to random networks, forming cohesive groups of interacting proteins acting on the same metabolic pathway. While in PPI the clustering coefficient reaches values greater than 0,4 on random networks is generally less than 0.01 with $p < 0,05$ (Rezende *et al.*, 2012; Folador *et al.*, 2016). Since there are several metabolic pathways in an organism, naturally there are several groups of proteins interacting more intensively in these pathways, giving the PPI a higher clustering coefficient.

Betweenness centrality: is a network centrality measure that calculates the proximity between the vertices in a graph, determining, among the shortest paths to cross the network, how many pass through the node. The higher betweenness value more shortest paths pass through node and enables cross the network side to side in a few steps. In PPI are proteins involved in different biological processes or metabolic pathways, connecting to several groups of proteins without necessarily be a protein hub.

Fig. 2 Sample of interaction degree distribution in scale-free (left) and random (right) networks. The red line indicates a perfect power-law.

However, some hub proteins, because they have many interactions and connect several modules, are also characteristic of betweenness (Pavlopoulos *et al.*, 2011).

The topological measures are features that should be present in PPI generated by experimental or computational methods, and are useful as a first layer to validate the predicted PINs by computational methods. Derived from graph theory, there are several other metrics that can be applied to PPI to extract some biological significance, however without validations described. Having a PPI these and other measures can be easily calculated, e.g., using Network Analyzer plugin (Assenov *et al.*, 2008).

Methods

To investigate protein interactions, both experimental methods in the laboratory (*in vitro* or *in vivo*) and computational (*in silico*) are used. An interaction can be identified by experimental methods or predicted by computational methods, considering biological premises. In the case of PINs, the methods can be classified into (i) low throughput when used to characterize only a few interactions or (ii) high throughput when used to characterize a large number of interactions. Each method class has advantages and disadvantages. Generally, low-throughput methods are more reliable in identifying the interaction while high-throughput methods are more sensitive and identify the entire interaction network.

Experimental Methods

Experimental methods for identifying protein-protein interactions are performed by *in vitro* or *in vivo* techniques. The challenge of the test methods is to identify interactions in their natural state, just they occur in a living cell, without changing properties of proteins or the environment where they are, so as not induce or suppress interactions that naturally would not occur.

Co-immunoprecipitation (Co-IP): Co-IP is able to identify interaction between proteins or even protein complexes by using beads attached to an antibody specific for a target protein, whose interactions we wish to know. The antibodies bound to beads and the cell media are arranged together, establishing the interactions: the target protein interacts with its natural partners and interacts with the antibody. By centrifuging process the complex formed by the bead, antibody, target protein and the partner interaction are pelleted and isolated. The supernatant proteins are discarded and the pelleted proteins can be identified by mass spectrometry or other technique (Lin and Lai, 2017).

Tandem Affinity Purification (TAP): Similar to Co-IP TAP is able to investigate the interactions as they occur in the cell environment and has low contamination rate, although a high-throughput method has an accuracy similar to low-throughput methods. The method consists of attaching the TAP tag to a bait protein, arranged together with other proteins in concentrations similar to that *in vivo*, allowing interactions are established and protein complexes formed. TAP has affinity to the purification column and retains the complex formed with the bait protein in the washing process, when discarded molecules not interacting in the complex. In another purification step, the protein complex is separated from TAP and isolated, allowing the characterization of proteins by mass spectrometry (MS-TAP) (Puig *et al.*, 2001). Due consecutive purification step the method have a deficiency: proteins participating weak or transient interactions may not detected by turning off from TAP complex.

Yeast two-hybrid (Y2H): The two-hybrid method is capable of identifying physical interactions of proteins. Y2H is a method that uses transcription machinery to express a reporter gene. The transcription factor is activated only when the proteins (bait and prey) interact, and the reporter gene is transcribed. Thus, the interaction is perceived by the expression of the reporter gene or its phenotype. Bait is a target protein anchored in the DNA-binding domain which in turn binds to the promoter region Upstream Activation Sequence (UAS) of DNA. Prey are the Bait partner proteins, anchored to the transcriptional activation domain (TA), which will be interrogated. When Bait and Prey interact the transcription process is activated and the gene reporter expresses (Ito *et al.*, 2001). This process can be reproduced on a large scale and investigate the entire interactome.

Bimolecular fluorescence complementation (BiFC): is a technology used to identify physical protein interactions. It is based on the use of a fragmented fluorescent protein (e.g., enhanced yellow EYFP) in two non-fluorescent peptides, respectively the N- and C-terminal peptides, each one attached to a specific known target protein by a linker. When these two target proteins expressed on the live cell interacts, the N- and C-terminal peptides became near and interact too, reformulating to the native three-dimensional structure da fluorescent reporter protein (e.g., EYFP). The emitted fluorescent signal can detected within the cell by an inverted fluorescence microscope making possible identify the location of interacting proteins and known the interaction type by the signal intensity (Wang *et al.*, 2017).

Cross-linking coupled with mass spectrometry (XL-MS): The cross-link are markers connecting a polymer chain to another (e.g., protein-protein), usually developed by the use of reagents or cell engineering and can modify the characteristics of the investigated protein or its natural environment. Several methodologies researching *in-vivo* interactions use different cross-link to identify the interaction. The cross-linking form covalent bonds and stabilizes the interaction between proteins, making it possible to identify even the weak or transient interactions by mass spectrometry (Holding, 2015).

Laser UV Cross-linking (LUCK): The major difference of the LUCK method is to use as cross-link the aromatic residues (Phe, Trp, Tyr). These residues are naturally present in most proteins, especially at binding sites, establishing strong bonds, having the advantage of not modifying the characteristics of the investigated protein or its natural environment. When irradiated with UV light these aromatic residues produce radicals that react and generate covalent bonds with near residues, making it possible

to identify even the transient interactions. The LUCK has already been used both to identify the formation of stable dimers of GAPDH in HeLa Cell (Itri *et al.*, 2016) as to detect the protein interaction between GAPDH and alpha-enolase in living cells (Itri *et al.*, 2017).

Fluorescence resonance energy transfer (FRET): is a method that uses different fluorescent proteins (FP) to identify interactions, having potential for unveils temporal and spatial information on proteins in living cells. Both FP are named donor and acceptor respectively, which when excited by a specific wavelength range emit in response a different specific wavelength range. Thus, considering a donor with excitation and emission peaks at X and Ynm respectively and a receptor with excitation and emission peaks at Y and Znm respectively, the interaction is identified when perceive peaks at Znm when excited at Xnm. Justified by energy transfer from donor to receiver when the signal emitted by the donor excites the near receiver.

Several other methods are described in the literature taking advantage of the physicochemical property for label proteins and permits identify interactions by diverse techniques, including sequencing transcripts as bPPI-seq method (Zhang *et al.*, 2017).

Computational Methods

The computational methods, also known as *in silico*, uses computational tools to solve biological problems also considered a more viable alternative due to its low cost when compared with experimental methods. Another advantage of *in silico* approaches is the high capacity to generate and analyze data inexpensively. Due to the rapid development in computing field is increasingly feasible the use of more powerful techniques to study biological networks.

The use of previously unviable or non-existent methodologies, such as the use of high-performance computing, has been increasingly frequent, as well as the emergence of new and more effective methodologies (Keskin *et al.*, 2016). Aided by the amount of information and biological data available added to the evolution of computers and algorithms have emerged methods for PPI prediction based on diverse approaches as binding strength between molecules, sequence alignment, phylogenetic trees, text mining, artificial intelligence and even using mixed approach.

Three-Dimensional Structure-Based Interaction Prediction

Bond strength methods use three-dimensional structures of two proteins to find a contact region (binding site) and measure the affinity between these two structures. In order, to reduce the computing power required for docking, usually the protein structures are considered a rigid body, differing from biological reality but enabling the prediction be performed quickly to a pair of proteins. Conversely, molecular dynamics considers the protein as a flexible body and besides calculating the affinity between molecules also calculates the angles of each atom taking into account the possible movements that the proteins can present recursively, consequently increasing the computational requirements. To achieve a few milliseconds with molecular dynamics, it takes days of processing, depending on the computational power available (Keskin *et al.*, 2016).

These methods are considered low throughput mainly for two reasons: (i) the high computational power and time required especially when using molecular dynamics technique, or (ii) a lack of three-dimensional structures determined experimentally to be used with docking or dynamic molecular techniques compared to the amount of available sequences.

The processing time can be considerably reduced when the docking or molecular dynamics programs are able to use the resources of the graphic processing units (GPUs) that, in addition to being accessible, are currently in the order of 5000 processing units, exceeding the amount of central processing unit (CPU) available on good and expensive servers. To take best advantage of both techniques, docking is usually performed to bind two proteins and then runs the molecular dynamics to optimize the interacting partner proteins in their less energy state.

A software widely used for molecular dynamics is GROMACS (Abraham *et al.*, 2015) while docking can be performed with HEX (Ritchie, 2003), MegaDock (Ohue *et al.*, 2014) and HADDOCK (De Vries *et al.*, 2010), SwarmDock Server (Torchala *et al.*, 2013), ZDOCK Server (Pierce *et al.*, 2014), Multi-IZerD (Esquivel-Rodríguez *et al.*, 2012), LightDock, ClusPro (Jiménez-García *et al.*, 2017; Kozakov *et al.*, 2017), among others.

In order to encourage the development of new algorithms and methods as well as to improve existing ones, the Critical Assessment of PRedicted Interactions (CAPRI) was created in 2000. The CAPRI is an open event that occurs in competition format to evaluate the algorithms in blind predictions of the structure of protein-protein complexes. Prior to publication, the organizers make available to competitors proteins offered by crystallographers as targets, without prior knowledge of the complex. The competitors perform the complex structure prediction by docking the individual components. Afterwards, the predicted models are submitted to evaluators compare the geometry and interaction site against the experimental models, scoring the best predictors.

Multiple Sequence Alignment (MSA)-Based Interaction Prediction

With the popularity of DNA sequencers, many genome projects were undertaken, and various organisms had their genome sequenced and annotated. Many genomes as their amino acid or nucleotide sequences are available in several public databases, and the GenBank, EMBL and DDBJ are the largest repositories of such information. In contrast to the low number of three-dimensional structures, the number of sequences in the public databases is extremely higher, favoring the scientific community that uses these sequences in their researches, including the prediction of interaction. A class of method uses multiple sequence

alignment (MSA) to predict protein-protein interaction and each is based on a biological premise that generally aims to identify conservation among the organisms' sequences using alignment software. They are:

Phylogenetic profile-based prediction (co-occurrence): The method is based on the biological premise that if two genes remain conserved when comparing several organisms, the respective protein translated from these genes will interact. This assumption becomes even stronger when both conserved genes are not present in one or more organisms compared, demonstrating selective pressure for both remain or be removed together from genome. The uncertainty in using this method is to identify how phylogenetically distant should be the organisms compared therefore, by selecting close organisms makes it difficult to identify whether proteins are conserved because they are under evolutionary pressure or simply because there has not been enough time to diverge. The more distant organisms are, the more reliable the prediction will be, but fewer interactions will be identified (Valencia and Pazos, 2002).

Neighborhood genes-based prediction: This method is an evolution of the previous one, considers the same premise and presents the same doubt, but considers that the genes, besides being conserved, must be neighbors. This method prioritizes to identify conservation of closer genes taking into account they tend to evolve in similar periods, like operons transcribed and translated at the same time, probably generating protein structures interacting in a same function or metabolic pathway (Valencia and Pazos, 2002).

Phylogenetic tree-based prediction (Mirrortree): The method is based on the biological premise that if two proteins interact they undergo similar evolutionary pressures and co-evolve in an organism (Zhou and Jakobsson, 2013). Thus, when comparing the same protein in several organisms, the respective interacting proteins, will present a similar phylogenetic tree, one mirrored in the other, representing similar evolution in the different organisms. However, proteins evolving differently may also interact and be disregarded by this method. To identify an interaction phylogenies of various proteins are made and, the phylogenetic trees presenting similar topology reveals the respective proteins participating in the interaction (Pellegrini et al., 1999). This can be made feasible by converting pairs of phylogenetic trees into distance matrix and calculating the correlation coefficient. Matrices with high correlation coefficient indicates a phylogenetic tree with similar topology.

Gene fusion-based method: The biological premise underlying this method is the existence of two genes (ga, gb) in an organism with functional domains homologous to a single gene in another phylogenetically close organism (gc), probably the proteins encoded by the two individual genes (pa and pb) interact physically to play their role, explained by an evolutionary process that led to the fusion of genes and translation of a single protein into another organism (pc). The homology between genes can be identified via sequence alignment and this assumption becomes even stronger when one perceives in multiple alignment a group of organisms presenting the two individual genes and another group presenting the fused genes (Zahiri et al., 2013).

Interolog Mapping

This method is based on the biological premise that if it is known the interaction between two proteins in a particular organism and exist both orthologous proteins in another organism, they probably also interact. It is a high throughput method by allowing mapping known available interactions from public databases to an organism of interest using sequence alignment. The mapping of the interactions is performed in two steps: (i) identification of the orthologous genes or proteins by aligning the sequences from public databases against the sequences of your organism and (ii) composition of the orthologous pairs of interacting proteins based on interactions from public database. Although simple, due to the large volume of sequences and interactions in some databases, in the order of millions, it may require considerable computational resource for the prediction process. The confidence of the predicted interaction will depend on two factors: (i) that truly homologous proteins are mapped and, (ii) how reliable is the known interaction from public databases. Despite being an effective and easy to use method, it is able to map the interactions already determined in other organisms, without the ability to predict new interactions not yet reported.

Text Mining

The text mining is a computational technique used to obtain important information recorded in texts such as abstracts or scientific articles, having commercial, governmental and scientific applications. Briefly, if an interaction is described in a text, it is theoretically possible to be identified using different algorithms. In summary, a described interaction theoretically can be identified using different techniques and text mining algorithms (Zahiri et al., 2013). The identification of interactions is performed in four steps: (i) download of library to be used in the research, in the case summaries and articles containing information about proteins or genes; (ii) identifying entities (genes or proteins) of interest; (iii) identification and verification of relationship between the entities in sentences and paragraphs, in the case indicating interaction; and (iv) extraction of entities to form the interaction pair. As interolog mapping this is a high throughput method able to identify interactions previously described, without the ability to identify new interactions. To reduce the sampling range and increase reliability in prediction, the literature is usually retrieved from a specific species, limiting the method to identify specific interactions. Another limiting factor is how the entities are described (e.g., the gene name, the protein name, codes from different databases), if untreated, can limit the method does not to identify all possible interactions and generate a lot of false-negative. However, it can be a very useful method, especially when it is desired to know the relation of the interactions, usually identified by action verbs in sentences (e.g., bind, interact, regulate), making it more informative. Interactions identified experimentally and published, when predicted by text-mining method and curated, in many cases have experimental equivalence, since it was first identified by an experimental method.

Machine Learning

Machine learning is an Artificial Intelligence subfield of the Computing area. The algorithms form models and patterns from sets of gold standard data where the different characteristics that determine an interaction are already known. The algorithms are executed in two steps: (i) learning, where the characteristics are observed and identified in a set of gold standard data whose interactions are known aiming to establish a pattern e ; (ii) prediction, where the characteristics are checked on a real data set to determine whether an interaction exists or not, or even establish a degree of confidence in the interaction. In PPI can be used diversified characteristics such as genetic or protein sequence, physicochemical data, three-dimensional structures, cellular location, binding sites, conserved regions or even the combination of these characteristics. Prediction confidence is dependent on learning, ie if the algorithm is able to learn and determine all the relevant characteristics for an interaction to exist, it will be able to infer whether an interaction is possible or not based on these characteristics. Due to the large number of interactions available, experimentally determined or not, it is possible to create a set of interacting proteins to train the algorithms (Dick *et al.*, 2017). For an efficient training, it is important to highlight and imperative the algorithm learns which characteristics determine an interaction, as well as the characteristics determining not interaction, that is, for the learning, besides a positive control set a negative control set is necessary. This is plausible since there are cured databases of proteins that do not interact as The Negatome Database (Blohm *et al.*, 2013).

Abstractly, we can break any prediction method down into.

Sample description: how each sample can be described to the method. Not everything is accepted by all methods. For instance, in simple linear regression, each sample can only be described by two numbers (x , y). *Model*: every method assumes a certain structure between the samples. For example, in linear regression, that assumption is that the set of samples can be somewhat accurately represented by a straight line. Clustering, on the other hand, assumes “related” samples are also “close” in the sample space. *Parameters*: variables of that prediction method. *Training*: is the process of finding the best parameters that fit the samples, for some interpretation of “best”, how to find the right (or best) parameters. Training might be “supervised”, where previously classified data is used to find the appropriate parameters, or it might be “unsupervised”, when no such premade classification exists. *Prediction*: how predictions are made. Different methods accept different kinds of questions and output their predictions in different ways. Questions may include: “Given a sample with incomplete data, what best fits the blanks?” or “How well does this new sample fit?”. Predictions might be in the form of an yes/no answer, a real number, a label, or a mix of any of these.

These categories will be used to describe the prediction methods above.

Linear regression

Sample description: two (simple linear regression) or more numbers (multivariate linear regression). Linear regression assumes certain statistical properties over the training samples. Those properties can vary depending on which regression is used out of many variants, but may include assumptions such as weak exogeneity or homoscedasticity. *Model*: samples are represented as a straight line that is approximately close to all samples. *Parameters*: a and b where $y = xa + b$. In simple linear regression, a and b are real numbers. In multivariate linear regression, a and b are $m/\text{cross } n$ matrices, where m is the number of independent variables and n the number of independent variables. *Training*: always supervised and accepting only positive examples. The number of published and used estimators are too great to list here, but includes the Ordinary Least Squares method, the Maximum-Likelihood Estimation, the Bayesian Linear Regression, and the Theil-Sen Estimator. *Prediction*: given how the training phase yields a line, the distance to that line is a natural metric to evaluate how fit any new sample is. New samples can be taken from the line. *Examples*: Logistic regression (a generalization of linear regression for discrete dependent variables) was evaluated against other five methods with 16 feature categories used for sample description, including: gene expression, GO molecular function, GO biological process, GO component, and essentiality (Qi *et al.*, 2006). Logistic regression was used to create a confidence score for experimental data on protein-protein interactions. The confidence score was calculated based on the results of Luminescence-based Mammalian IntERactome (LUMIER), Mammalian Protein-Protein Interaction Trap (MAPPIT), Yeast-2-Hybrid (Y2H), Yellow Fluorescent Protein (YFP), Protein Complementation Assay (PCA), and a modified version of the Nucleic Acid Programmable Protein Array (wNAPPA) assays (Braun *et al.*, 2009).

k-means clustering

Sample description: each sample is described by a real vector with a fixed dimension. *Model*: the sample space is partitioned into k clusters and each sample belongs to a single cluster. Sample variance is minimized within a single cluster (Bishop, 2006). *Parameters*: the centroid of each cluster. *Training*: supervised, unsupervised, or a mixture of both. In the worst case (unsupervised), finding the absolute best centroids is NP-hard, requiring training to run for a time proportional to the exponential of the number of samples. Because of this, heuristics are usually used, giving “good enough” centroids most of the time. *Prediction*: k-means clustering naturally classifies samples in one of k categories. The centroid also serves as the archetype of each cluster. *Examples*: Mohamed and colleagues (Mohamed *et al.*, 2010) used k-means clustering where each sample, describing a protein-protein interaction, was represented by a vector with 27 dimensions describing features such as GO molecular function, GO biological process, GO component, and sequence similarity. K-means clustering was used as a method for dimension reduction, where each sample was the result of multiple liquid chromatography-mass spectrometry (LC-MS) alignments, each giving noisy indications of protein-protein interactions (Rinner *et al.*, 2007).

Hierarchical clustering

Sample description: anything with a meaningful distance function. *Model:* a hierarchy of clusters. Each cluster may encompass samples and other clusters, but each cluster can be encompassed by at most a single parent cluster. *Parameters:* edges and internal nodes, forming a tree. *Training:* supervised, unsupervised, or a mixture of both. Two strategies are usually used: agglomerative, where samples are grouped into clusters, or divisive, where a cluster encompassing all samples is recursively subdivided. There are many ways to decide whether to agglutinate or split, called the linkage criteria, including Complete-Linkage Clustering, Single-Linkage Clustering, and Minimum Energy Clustering. *Prediction:* the training result cannot be directly used for prediction. Instead, any new sample is added to the initial sample set and clusters are regenerated. *Examples:* Brohée and colleagues (Brohee and Van Helden, 2006) evaluates different clustering algorithms for protein-protein interaction networks. General properties of protein-protein interaction networks are noted based on their hierarchical clusters (Yook et al., 2004).

Support vector machine (SVM)

Sample description: each sample is described by a real vector with a fixed dimension. *Model:* samples separated into two areas by a hyperplane, optionally put in a transformed space. *Parameters:* a hyperplane, the minimum separation between the hyperplane and training samples (soft margin), and an optional transformation function (Haykin, 1994). *Training:* supervised only. Given a set of positive and negative samples, the parameters of usual transformation functions and the hyperplane can be found by solving a quadratic optimization problem, which is NP-hard and takes exponential time relative to the number of samples. Iterative alternatives include Sub-Gradient Descent and Coordinate Descent. *Prediction:* any sample can be classified as positive or negative by applying the transformation and checking whether the transformed point lies in the positive or negative half-space. Extensions allow for a broader classification than only positive/negative. *Examples:* Guo and colleagues (Guo et al., 2008) uses an SVM to model and predict protein interactions based on many physicochemical properties of their amino acids: hydrophobicity, hydrophilicity, volumes of side chains of amino acids, polarity, polarizability, solvent-accessible surface area, and net charge index of side chains of amino acids. Koike and colleagues uses a SVM to predict the interaction sites of proteins based on their sequence of amino acids (Koike and Takagi, 2004).

Hidden markov model (HMM)

Sample description: a sequence of symbols in a fixed alphabet. The alphabet need not be ordered (Bishop, 2006). *Model:* an HMM is composed by a set of distinct states, a set of normalized (summing to 1) probabilities for the state to change from any state to any other state (including itself), and a set of normalized probabilities that an observation occurs given a state. Alternatively, an “observation” can be seen as a letter in an appropriate alphabet that the model “emits” one at a time based on its current state and a random number. *Parameters:* transition and observation probabilities. *Training:* supervised or unsupervised. Given a set of states and possible observations (or emissions), the expectation-maximization algorithm is usually used to, iteratively, find the set of probabilities. Finding the “best” probabilities is possible but there is no known efficient algorithm for that as the problem is NP-hard. *Prediction:* a trained HMM can score sequences based on their similarity to sequences used in training. HMMs can also run in reverse, giving sequences that are likely similar to the ones used in training. *Examples:* In (Wojcik and Schächter, 2001), HMMs are used to predict protein-protein interaction (PPI) maps given a PPI map of another organism. Eddy (Eddy, 1998) gives a review of Profile Hidden Markov Models (pHMM) which can perform sequence alignment based on similarity to certain sequences.

Artificial neural network (ANN)

Sample description: any type of data with a fixed size. Depending on how the network is built, variably-sized data can be used as well (Haykin, 1994). *Model:* a set of artificial neurons forming a network, where each one combines, transforms, and filter incoming data, passing the result forward. *Parameters:* network topology, which can be premade, and parameters for each artificial neuron. *Training:* supervised and unsupervised. Training procedure is highly dependent on network type and topology, but most used are Gradient Descent, Simulated Annealing, Evolutionary Algorithms, Particle Swarm Optimization, and others. Training an ANN usually takes considerable computer resources and time. *Prediction:* any kind, depending on topology and how it was trained. *Examples:* An ANN is used to predict interaction sites between proteins given a sequence of aminoacids (Ofra and Rost, 2003). Protein are given a predicted function with an ANN. The authors also suggest that predicted function can be used to validate protein-protein interaction databases that might contain false negatives (Jensen et al., 2002).

As each predictive computational method considers different biological premise, it can of course disregard biological factors relevant to identification of interaction, thus, a good practice, is to use predictive computational methods together in order to guarantee greater sensitivity in the PIN predictions. This strategy besides useful to add information to the PIN is useful to validate interactions, because an interaction identified by more than one method reduces prediction by chance and increases the probability of being true interaction. Similarly, when possible, using both experimental and computational methods can also aggregate information to the PIN.

Different methods predicted PINs for various organisms whose interactions usually are deposited in public databases.

Public Databases

Aiming to make public and share data interactions for the scientific community, several databases were designed, containing interactions identified in different organisms by experimental and computational methods. With the wide variety of organisms and methods for PPI prediction also came the need to distinguish these public databases reliability of interactions. Thus, arose in September 2005 the International Molecular Exchange Consortium (IMEx) as an international collaboration having as participants several public databases joining efforts to validate protein-protein interactions through curation, ensuring a detailed and highly reliable set of non-redundant interactions to be made publicly available (Orchard *et al.*, 2012).

Public databases store and provides physical or functional interaction data experimentally characterized or predicted computationally or even cured, some store interaction of various organisms while others store specific organism interaction or even specialized in biological process or functionality (Table 1).

The classes of positive and negative interactions are important biologically but also computationally. Besides being useful at systems biology level for better understand an organism, they serve as training data for machine learning algorithms, still useful as the gold standard to validate computational predictive methods (Dick *et al.*, 2017). More details of methods and databases can be observed in the work of Rao and colleagues (Rao *et al.*, 2014).

The Minimum Information About a Molecular Interaction Experiment (Mimix)

Recently, to publish a PIN article, magazines began to suggest the interactions identified in the experiments were deposited in a public database, a great initiative to provide and share information with the scientific community. However, with the diversity of databases, it was also realized the need to standardize the information concerning the PIN experiments that would be deposited aiming to facilitate the comparison, exchange and verification between these databases. Thus, was developed a guide advising how to describe a molecular interaction experiment and which information it are important (Orchard *et al.*, 2007), available on the HUPO Proteomics Standards Initiative – “see Relevant Website section” (access in 2017-10-26).

Thus, interactions from the most diverse experiments, studied and applied for biological purposes are deposited in the various public databases.

PIN Applications

The PINs have various biological applications such as providing subsidies for characterization of hypothetical proteins; understand systematically an organism, process or metabolic pathway; identification of key proteins or even suggest potential targets for developing new drugs.

Protein Annotation

The no knowledge about the function of certain proteins prevents the understanding of an organism in relation to its development, proliferation, virulence and biological processes thus, annotation of hypothetical proteins is essential for a better

Table 1 Protein-protein interaction public databases

Name	Organisms	Interaction type (Física/funcional)	Protein and interaction amount	Method type (Experimental, computacional)	Curated	Link

Negatome v 2.0	non-interacting protein	Phy	P: N/A I: 30,756	Co	Yes	http://mips.helmholtz-muenchen.de/proj/ppi/negatome/

understanding of the organism. Generally, protein annotation is performed by sequence alignment and homology identification against proteins from public databases, but even with the large number of sequences not all proteins have their function annotated, requiring other approaches.

Currently, proteins having similar or complementary functions are known to be in close proximity on genome and tend to be transcribed together such as operons. Thus, it is expected these proteins are located in a cluster on the PIN and are closely connected among themselves (Pellegrini *et al.*, 2004).

As PIN provides knowledge of the various proteins working together in biological processes, it is sometimes possible to deduce the function of a hypothetical protein based on the function of its interaction partners in the cluster (Marcotte *et al.*, 1999). This method was applied in *Eriocheir sinensis* and based on PIN modularity feature the functions of 677 proteins were annotated (Hao *et al.*, 2015).

System Biology

The identification and annotation of IPP is important to understand how proteins form complexes to perform tasks inside the cell, subsidizing to understand by the set of interactions, how the organism works systematically. A metabolic pathway can be defined as a set of actions or interactions between genes and their products that results in the formation or change of some component of the system, essential for the correct functioning of a biological system. Thus, the identification of molecules and pathways in which they are involved is essential in the studies seeking to discover mechanisms involved in phenotypes and diseases (Hu *et al.*, 2017).

The PIN use is becoming increasingly common and essential for helping to elucidate biological processes clarifying the molecular origins of many diseases. As interactions are extremely disturbed by diseases such as cancer, heart disease and neurodegenerative diseases, the data generated by PIN provides identifying reasons to study them in living cells, enabling more accurate results and near reality (Itri *et al.*, 2017).

Based on gene modules constructed from human PINs to measure the relationship between pathways, a total of 2143 KEGG pathway pairs with close connections were identified, whose results were consistent with available evidence. The method was applied to explain the potential pathway targets that may be important in the etiology and development of Parkinson's disease (Hu *et al.*, 2017). The PIN usage in *Borrelia burgdorferi* allowed to discover two proteins with important functions related to infection and the biology of the organism, having different binding sites the interaction between proteins controls the infectivity of the organism (Thakur *et al.*, 2017).

PINs are important tools enabling better understanding of an organism mainly when added to other layers of functional and experimental data such as cell location or gene expression.

Essential Proteins

For optimal functioning the organism needs proteins guaranteeing primary resources for survival, and the lack or diminution of these proteins may be deleterious (Winzeler *et al.*, 1999). High-interaction proteins (hubs) are usually related to the essential genes in organisms, having important cellular functions form densely connected clusters whose removal causes a great rupture in the PIN and the organism may not perform its basic functions (Pavlopoulos *et al.*, 2011).

Recently *in silico* experiment showed the hub proteins are correlated with essential genes, they are highly conserved among species and possess low mutation rate, probably due to strong evolutionary pressure receiving (Dilucca *et al.*, 2017). With these features, the hub proteins are potential targets for drugs, offering new possibilities to research effective drugs for pathogenic organisms (Becker and Palsson, 2005).

Another *in silico* work identified 181 hub protein in nine *Corynebacterium pseudotuberculosis* strains, 180 with proven essentiality in other organisms. Because they were highly conserved, only 41 had no homology to the host and were considered promising targets for drugs (Folador *et al.*, 2016).

Host-Pathogen Interaction

The PINs still provide the possibility to investigate host-pathogen interactions and can be applied to understand the relationship between pathogen and host at systems biology level as suggesting proteins or interactions as potential targets for drug. Aspects related to virulence such as adhesion, escape of the immune system, proliferation are often dependent on the host-pathogen interaction and the knowledge of these mechanisms, even partially, can be determinant to understand the infection and to guide new experiments.

In addition to intracellular PIN, should be considered spatio-temporal aspects of host-pathogen PIN prediction, that is, the proteins participants of interaction must coexist and must be in cellular location favoring interaction, being potential participants in host-pathogen interaction the membrane, transmembrane or secreted proteins. The identification of host-pathogen interaction mainly promotes research into new interaction-inhibitors drug preventing infection be harmful to the host.

The host-pathogen PINs were used to identify interactions among *Mycobacterium tuberculosis* and *Homo sapiens* (Huo *et al.*, 2015). Using the SVM method was predicted the PIN of viruses with *Homo sapiens* as interactions of both hepatitis C virus and papillomavirus against humans obtaining 80% accuracy (Cui *et al.*, 2012).

In the study between *Nipah* virus and *human* 101 interactions were identified, 88 never found previously, being the main targets the miRNA processing machinery and the preprocessing factor of mRNA PRP19, including proteins capable of altering the p53 gene expression (Martínez-Gil *et al.*, 2017). Many targets for existing drugs are contained in a small number of families as guanine nucleotide-binding protein (G-protein) – acute receptor, nuclear hormone receptor, ionic channel kinase, and protease.

New Drug Classes

Many targets for existing drugs are contained in a small number of families as guanine nucleotide-binding protein (G-protein) – acute receptor, nuclear hormone receptor, ionic channel kinase, and protease (Groom and Hopkins, 2002; Santos *et al.*, 2017). Discovering new drugs has become a difficult task as known targets in the human proteome are increasingly limited being PINs the future targets for new drug discovery (Shin *et al.*, 2017). To overcome the difficulty to find new targets for drugs, researchers expect PIN become drug targets for diseases not yet having effective treatments such as Parkinson's and Alzheimer's disease (Milroy *et al.*, 2014). It is estimated in the human interactome there are between 130,000 and 650,000 interactions being drug targets only a small percentage (Venkatesan *et al.*, 2009; Rognan, 2015). Only in recent years more than 40 interactions were targeted and many inhibitors are in clinical trials phase (Arkin *et al.*, 2014), however, more than 90% of the interactions in humans have not yet been deciphered, having wide scope for research and improvement of predictive methods (Shin *et al.*, 2017).

Classical drugs tend to inhibit proteins that are sometimes essential in other biological processes and can cause adversities by not acting on an exclusive component (Petrakis and Andrade-Navarro, 2016). Due to the great structural and conformational variability the interactions emerge as an important target for specific drug development that act by stabilizing or inhibiting a distinct interaction sites of an exclusive component (Bultinck *et al.*, 2012). An example is the use of docking to identify inhibitory molecules of the Aurora Kinase-TPX2 PPI and prevent the growth of malignant tumors such as colon and stomach cancer, preventing the multiplication of cancerous cells (Cole *et al.*, 2017). Research combating cancer identified the molecules NVP-CGM097 and NVP-HDM201 with affinity to MDM2 and with potential p53-MDM2 PPI inhibitor, already in phase 1 clinical development (Holzer, 2017). A successful example is the SMPPiIs inhibitors acting on bromodomain, four in clinical trials for cancer (I-BET762, CPI-0610, Ten-010 and OTX15) for the potential of binding to the bromodomain hydrophobic core and inhibiting the interaction between the two parts of bromodomo-histone (Arkin *et al.*, 2014).

The NusB-NusE interactions, fundamental to the formation of stable complexes required for RNA transcription, have antibiotic activity and are potential emerging antibacterial targets (Cossar *et al.*, 2017). Another example is 14-3-3s family proteins, abundant in the central nervous system, bind to serine and threonine regions when phosphorylated, are related to certain diseases and the use as a target for drug showed therapeutic effects (Kaplan and Fournier, 2017).

However, the identification of molecules inhibiting or stabilizing interactions presents challenges, mainly because they do not present traditional drugs characteristics as the Lipinski's five rules. The PPI interfaces are distinct from traditional targets, both geometrically when because the interactions are largely dominated by hydrophobic atoms (Shin *et al.*, 2017), being the natural compounds products potent candidates in the drug design targeting protein interface (Jin *et al.*, 2017).

Conclusions

Besides the work explained in this article, there are other public databases containing PINs from a diversity of sources, specialized in some specific organism. Similarly, there are other methods for identification or prediction of PINs and following technological developments, others are likely to be developed. Regardless of whether it is experimental or computational, low-throughput methods present greater scientific reproducibility than high-throughput methods, identifying large scale interactions. The low reproducibility of high-throughput experimental methods is probably due to the inability to reproduce a physico-chemical cellular environment similar to that occurring *in vivo*, especially with respect to variables that are not easily controlled as the space and time the interactions are carried out. For high-throughput computational methods, the low reproducibility is mainly motivated by the different and specific biological approach of each method, which use different logic, algorithm or data input, consequently generating different results. This shows that we still have a lot to learn and develop until we get PINs similar to those in nature.

PINs are applied for various purposes ranging from understanding an organism, understanding a metabolic pathway or process systematically, identifying proteins or interactions with potential use as a target for drugs or even understanding the relationship between pathogen and host. However, in order to obtain better results, it is not enough to only have PINs, it is necessary to aggregate layers of information from the different omics to the network, making possible a more complete interpretation within a biological context. Although, there are tools for visualization, formatting and analysis of PINs, the biological interpretation is usually done by a specialist researcher, with a broad knowledge of the biological context for which the network was built or knowledge about the organism. A PIN is not usually the final object of a search, but rather a tool that helps researcher in the organization, visualization, and integration of data to generate knowledge. Combining the researcher's expertise and knowledge, a PIN can serve to raise new hypotheses and to direct more assertive experiments in the laboratory.

Prediction of Protein-Protein Interactions: Looking Through the Kaleidoscope

Anna Laddach, Sun Sook Chung, and Franca Fraternali, King's College, London, UK

© 2019 Elsevier Inc. All rights reserved.

Glossary

Asymmetric unit The smallest protein unit that can, by duplication and symmetry operations, generate a multimeric Protein Data Bank (PDB) structure.

Biological unit The functional protein unit of a PDB structure.

B-factor Also called temperature value, is associated with the spread of the measured electron density of an atom. It describes the uncertainty associated with the position of an atom in a crystallographic structure.

Interface core Amino acid residues which localise to the centre of a protein-protein interface and are fully buried upon interface formation.

Interface rim Amino acid residues which localise to the periphery of a protein-protein interface and are not fully buried upon complex formation.

Homologs Genes/proteins which share a common ancestor. A threshold sequence identity of 30% is normally used to detect homologs.

Obligate interaction A permanent interaction between proteins which cannot form stable structures on their own.

Orthologs Homologs which have arisen through speciation and perform similar functions in different species.

Paralogs Homologs which have arisen through a gene duplication event and have (generally) evolved to perform distinct functions.

Permanent interaction An interaction which is usually very stable and only exists in its complexed form.

Protein core The interior of a folded protein structure which is not exposed to solvent.

Protein interaction interface Regions of separate proteins which directly contact one another on complex formation.

Protein surface The surface of a protein structure which is exposed to solvent.

Solvent accessible surface area (SASA) The surface area, of a protein 3D component, which is exposed to solvent. Normally calculated at the residue level.

Transient interaction An interaction which can be formed briefly in the cell and in a reversible manner. Can be further classified as strong transient or weak transient based on measured interaction affinity.

Introduction

The genomic revolution of the past few decades has pushed technology to deliver efficient and precise tools for the fast and accurate mapping of genes in the genomes of thousands of species (Koepfli *et al.*, 2015). As a consequence, our knowledge of the human gene atlas is quite exhaustive (Telenti *et al.*, 2016). But knowledge without understanding has limited use. What one would aim for is to master the functional relationships between these genes, and their complex communication wired in a cellular context. The gene products, proteins, play an important role in this communication and in the networking capability of the cell; in this sense, they have been rightly defined as the workhorse of the cell. Therefore one of the next challenges is an exhaustive discovery of protein-protein interactions (PPIs) and the molecular aspects which play a role in their functional interplay. However, mapping the landscape of this multidimensional space of interactions is challenging, and techniques used to date vary in both complexity and efficacy. Recent renewed efforts, both in the theoretical and experimental fields, have been promoted by a number of studies which have challenged PPI detection techniques, such as Yeast Two-hybrid (Y2H) and Mass Spectrometry, to deliver much more accurate datasets for binary PPI maps (Fessenden, 2017). Data collected by the Human Proteome Project, since 2010, have recently (Feb 2016) achieved a coverage of 82% of this proteome, identifying altogether more than 90,000 unique protein interactions (Deutsch *et al.*, 2015). In spite of this progress, there is little overlap in the interactome uncovered by different experimental techniques (Fernandes *et al.*, 2010; Drew *et al.*, 2017). We are therefore obliged to look at these detailed snapshots as through a kaleidoscope and store, catalogue and assemble the unique pictures they display. From these, one can generate accurately annotated sub-sets of proteins and testable hypotheses, which can help in assigning confidence to functional modular units that play a role in the cellular machinery (Fessenden, 2017; Chung *et al.*, 2015).

Unfortunately, the large scale experimental probing of protein-protein interactions is both time-consuming and costly. However, computational methods can play a large role in filling the gap between gene knowledge and the functional communication. Moreover the results of such computational predictions can be validated by targeted experiments, thereby making more efficient use of experimental resources (Havugimana *et al.*, 2012; Carlin *et al.*, 2011).

Computational approaches to the study of PPIs include automated literature curation to generate large databases, such as STRING (Szklarczyk *et al.*, 2015) and the exploitation of sequence similarity/evolutionary relationships in order to both predict and extend functional knowledge of PPIs. Moreover further features, including the physicochemical properties of the interacting protomers, can be incorporated in methods to predict protein-protein interactions. Protein structural information, deposited in the PDB, has recently been exploited to add reliability to the collected interactions. Here, the structural coverage of the network has been extended through the large-scale homology modelling of binary interaction complexes (Mosca *et al.*, 2013). Recent work

using machine learning techniques and Bayesian approaches (Garzon *et al.*, 2016) has considerably progressed the field of protein-protein interaction prediction combining multiple scores, such as those based on protein abundance, expression profiles and partner redundancy and coarse grained structural modelling, along with the previously described features. Structural information on single protomers is also being used in docking procedures to predict and score binary complexes. These methods have considerably improved in the recent years (Xue *et al.*, 2015; Gromiha *et al.*, 2017) but are still dependent of some prior information on the binding features.

As the protein-protein interaction space covered by amalgamating data from 90 experimental investigations is sparse, it is becoming clear that effective data integration from multiple sources with different granularity, including computational analyses, can play a determinant role in expanding the known interactome and laying the foundation for improved predictions (Moal *et al.*, 2017). In this article we will give an overview of current methods for determination and prediction of PPIs, with a particular focus on predicting interfaces of interaction complexes and their structural properties.

Experimental Techniques and Data resources

Computational analyses of PPIs can extract useful information for the interpretation and prediction of properties that characterise PPIs. It is therefore important to be aware of the experimental source used for data determination, as this can impact on its underlying quality and accuracy. Moreover, an interaction can be considered more reliable if its existence is supported by multiple experimental techniques. This section briefly describes the most commonly used experimental methods for the detection of protein-protein interactions, highlighting the advantages and limitations of the different techniques, and recent advanced data resources, which have constructed protein-protein interaction networks from large-scale human proteome studies. These have stimulated the creation of integrative databases which make the results accessible to users.

Yeast Two-Hybrid (Y2H)

The yeast two-hybrid method (Two-hybrid screening) is the most widely used assay for detecting binary protein-protein interactions. It has been developed, refined and adapted to large-scale studies (Dufree *et al.*, 1993; Vidal *et al.*, 1996) since first introduced (Fields and Song, 1989). Two protein domains are tagged as a DNA binding domain (DBD) (bait protein) and an activation domain (AD) (prey protein) both of which are required for the transcription of a reporter gene and thus their interactions are inferred by expression of this reporter gene (Ito *et al.*, 2001). The Y2H method and its applications have been largely exploited to provide high-throughput protein-protein interaction (PPI) information, however some technical limitations persist. These are mainly caused by the lack of specificity between bait and prey, which may cause false-positive and false-negative interaction detection (Rao *et al.*, 2014; Westermarck *et al.*, 2013).

Affinity Purification Coupled with Mass Spectrometry (AP-MS)

Affinity Purification coupled with mass spectrometry (AP-MS) can identify protein complexes by directly purifying the protein of interest from cell lysates. This is followed by identification of the protein or proteins present by mass spectrometry analysis (Bantscheff *et al.*, 2007; Gingras *et al.*, 2007). Recent biotechnological advances (Konermann *et al.*, 2014; Yates, 2013) have overcome earlier problems such as specificity (segregation of over-expressed proteins or epitope-tagged proteins into abnormal cellular compartments) and co-purification of contaminating proteins (Rao *et al.*, 2014; Westermarck *et al.*, 2013).

Co-Fractionation Mass Spectrometry (CF-MS)

While the AP-MS method has been used to detect labelled bait proteins and the proteins with which they associate, it is limited to the identification of proteins for which antibodies are available or reliable epitope-tagged expression can be achieved. A Co-fractionation Mass Spectrometry (CF-MS) method has been developed to overcome such limitations, and establish comprehensive, less biased, protein associations of endogenous cellular proteins (Havugimana *et al.*, 2012; Kristensen *et al.*, 2012). The method involves preparing cellular lysates under mild, non-denaturing conditions. Soluble protein complexes in these lysates are then separated by several biochemical fractionation procedures, such as high-performance ion exchange chromatography, size-exclusion chromatography or isoelectro focussing. Fractions from each biochemical purification method are collected, trypsinized and the proteins present are identified by mass spectrometry analyses of each fraction. The components of each protein complex that co-fractionate are calculated by statistical and computational methods (Havugimana *et al.*, 2012).

3D Structures: X-ray, NMR, Cryo-EM

Accurate atomic detail of single and protein assemblies is regularly stored in the Protein Data Bank (PDB) (Berman *et al.*, 2000), the largest archive of structural data for biological macromolecules. The number of entries has increased rapidly due to progress in the techniques of X-ray crystallography, Nuclear Magnetic Resonance Spectrometry (NMR) and Cryo-electron

microscopy (cryo-EM) (Callaway, 2015) (60,332 homo-/hetero-mers among 121,046 protein structures, May 2017), however coverage of the human proteome and interactome is still incomplete (see Table 1).

PDB entries annotate possible assemblies of the characterised proteins. The asymmetric unit refers to the smallest protein unit that can, by duplication and symmetry operations, generate the multimeric structure. This result may actually not be related to the biological role of complex. On the other hand, the biological assembly is annotated as such if it has been shown, or predicted, to be the functional unit (Krissinel and Henrick, 2007). Thus, to understand the functional role of a structure, it is preferable to refer the biological assembly, whenever possible.

PDB entries annotate possible assemblies of the characterised proteins. The asymmetric unit refers to the smallest protein unit that can, by duplication and symmetry operations, generate the multimeric structure. This result may actually not be related to the biological role of complex. On the other hand, the biological assembly is annotated as such if it has been shown, or predicted, to be the functional unit (Krissinel and Henrick, 2007). Thus, to understand the functional role of a structure, it is preferable to refer the biological assembly, whenever possible.

Large-scale Human Proteome Studies

There have been an increasing number of high-throughput PPI studies published recently, which made use of the methods described in Sections Yeast Two-hybrid (Y2H), Affinity Purification Coupled with Mass Spectrometry (AP-MS), Co-fractionation Mass Spectrometry (CF-MS). For human protein networks, four accurate large-scale studies from different research communities, which applied different technologies such as Y2H (Rolland *et al.*, 2014), AP-MS (Hein *et al.*, 2015; Huttlin *et al.*, 2015) and CF-MS (Wan *et al.*, 2015), have been published. In spite of the fact that each dataset covers three to seven thousand proteins, with considerable overlap in protein content (30% to 68%), their overlap in protein interactions is still very limited (3% to 6%) (Drew *et al.*, 2017).

Public Databases

The need for reliable and public protein interaction data sources due to the progress in the technologies used to detect protein interaction information, has stimulated the development of a number of databases in recent years (Chatr-Aryamontri *et al.*, 2015; Orchard *et al.*, 2014; Szklarczyk *et al.*, 2015). These 180 rely on a collaborative effort throughout the International Molecular Exchange (IMEx) consortium (Orchard *et al.*, 2012) which develops solid data formats and defines curation rules to improve data integrity. Not only integrative databases, but also databases specifically tailored for structural annotations on protein-protein interaction networks, have been developed (Mosca *et al.*, 2013; Lu *et al.*, 2016) (Table 2).

Table 1 Structural coverage of the human protein-protein interaction network; statistics taken from Interactome3D

	Total	With structure	With model	Without structure
Proteins	14190	1843 (13.0%)	7600 (53.6%)	4747 (33.5%)
Interactions	95152	5757 (6.1%)	5978 (6.3%)	83417 (87.7%)

Table 2 Examples of public PPI databases

Name	Key features	Public website
IntAct (Orchard <i>et al.</i> , 2014)	Protein interaction data repository curated from the literature and direct experimental results Updated monthly	http://www.ebi.ac.uk/intact/
BioGRID (Chatr-Aryamontri <i>et al.</i> , 2015)	Curated set of physical and genetic interactions including chemical associations and post-translational modifications Updated monthly	https://thebiogrid.org/
STRING (Szklarczyk <i>et al.</i> , 2015)	Known and predicted protein-protein interactions Main sources: High-throughput lab experiments, genomic context prediction, Co-expression, automated textmining, other knowledge databases	https://string-db.org
Interactome3D (Mosca <i>et al.</i> , 2013)	Structural annotation of protein-protein interaction networks from the available three-dimensional structures and modeling	http://interactome3d.irbbarcelona.org/
PinSnps (Lu <i>et al.</i> , 2016)	Genetic variant data mapped to a 3D integrated protein-protein interaction network	http://fraternalilab.kcl.ac.uk/PinSnps/
PrePPI (Garzon <i>et al.</i> , 2016)	Large scale database of interactions predicted by combining structural and non-structural methods	https://honiglab.c2b2.columbia.edu/PrePPI/

Features of Protein-Protein Interactions

The wealth of experimental data, described in Section Experimental Techniques and Data Resources, in addition to sequencing data, has been mined to uncover features which are characteristic of protein-protein interactions. These features are the key ingredients which have been exploited to predict both new interactions and interaction interfaces. Here we describe these features, followed by an account of how different approaches use such features in Section Computational Approaches to Predicting Protein-Protein Interactions.

Homology and Conservation

Since the late 80s, homology modelling has been used to infer the structure of proteins which lack experimentally resolved structures (Chothia and Lesk, 1986; Blundell *et al.*, 1988). This has played an important role in expanding the structural coverage of the proteome, as known protein sequences currently greatly outnumber experimentally solved structures (as described in Section 3D Structures: X-ray, NMR, Cryo-EM).

Importantly, this approach can be extended to expand the structural coverage of known or putative protein-protein interactions (see Fig. 1(a)); however, the coverage of known interactions by experimentally resolved binary complexes is even smaller (see Section 3D Structures: X-ray, NMR, Cryo-EM). The proviso must also be taken that, although interaction interfaces are generally conserved, a number of homologs have been observed to interact using different interfaces (Aloy *et al.*, 2003; Xue *et al.*, 2011) (see Fig. 1(c)). This is particularly the case when proteins are paralogs (proteins which have arisen through gene duplication which generally perform distinct functions (Pearson, 2013) rather than orthologs. The exact degree of interface conservation also appears to depend on a number of parameters associated with the nature of the interaction, e.g. binding sites of obligate interactions tend to be highly conserved and those of transient interactions less conserved (Xue *et al.*, 2011) (see Fig. 2 for a summary of interaction types). It has also been shown that homologs tend to interact using the same interface, even if the interaction partner is different (Esmailbeiki *et al.*, 2016) (see Fig. 1(b)). However, partner-specific interfaces have been shown to demonstrate greater conservation than generic interfaces, even with respect to those occurring in transient interactions (Xue *et al.*, 2011).

Homology-based approaches are rooted in the knowledge that, during evolution, constraints arising from protein structure and function impact on the conservation of residues (and therefore sequence identity). A classic example is that residues which reside in the core of a protein tend to be more conserved than surface residues. This is because such residues often play a crucial role in maintaining the fold of the protein and thus mutations which localise to this region are generally selected against (Echave *et al.*, 2016). Protein interactions represent another type of constraint, both structural and functional. A protein must maintain a structure which allows it to sterically and physicochemically interact with its partners; the affinity and kinetics of an interaction must also be suitably maintained so

Fig. 1 Scenarios exploring the relationship between interface similarity and homology. Letters refer to protomers which form binary interaction complexes and the prime symbol is used to denote homology. (a) Homologs A' and B' use the same interface as A and B, (b) homolog A' uses the same interface to interact with a protein which is unrelated to B, (c) homologs A' and B' interact via a different interface, (d) non-homologous proteins D and E use similar interface due to similar structural properties).

Fig. 2 Schematic showing interaction types. Obligate interactions refer to permanent complexes composed of protomers that are not stable on their own (see Glossary of terms).

that biological function is not disrupted. Indeed, it has been shown that surface residues which are involved in protein interaction interfaces are more highly conserved than non-interacting surface residues (Choi *et al.*, 2009; Ashkenazy *et al.*, 2016). An important observation, recently exploited in the prediction of protein interaction interfaces, is that when mutants do localise to an interface, this can result in the selection of compensatory mutants on opposing interface. This phenomenon, which is essentially due to co-evolution of the residues at the interface, allows functions abrogated by the initial mutation to be “rescued” by the compensatory mutation on the opposite side of the interface (de Juan *et al.*, 2013; Bitbol *et al.*, 2016).

Notably, it has also been shown that convergent evolution can take place. Here non-homologous proteins develop similar interaction interfaces (from a steric and physicochemical perspective) in order to interact with the same interaction partner (see Fig. 1(d)). An example of this is the mimicry of host protein interfaces by viral proteins in order to hijack host cell functions (Zhao *et al.*, 2011).

Protein Domains

In the vast majority of cases interactions do not involve entire proteins but rather specific regions, termed domains, which interact with one another (Raghavachari *et al.*, 2008). Therefore knowledge of a proteins underlying domain-architecture can aid in the prediction of both interactions and interaction interfaces, as discussed in Section Structure-based predictors.

Domains can be described as units within a protein which have a distinct structure or function, can fold independently, and can evolve with a degree of independence from one another. A number of resources define protein domains, including CATH (Sillitoe *et al.*, 2015), a structure-based classification system, and PFAM, which makes use of evolutionary information to infer domain boundaries (Finn *et al.*, 2014). Correct domain definitions are particularly crucial when dealing with large multi-domain proteins, such as titin (Laddach *et al.*, 2017).

Protein Recognition Mechanisms

Three different models exist to describe the nature of protein protein interactions (see Fig. 3). The lock and key model, originally proposed by Emil Fischer, describes interactions which are rigid in nature (Kastritis and Bonvin, 2013a; Fischer, 1894). Here both interaction interfaces are complementary in shape and negligible conformational changes take place on binding. In contrast the induced fit model involves conformational change on binding, allowing proteins with varying degrees of shape complementarity in the unbound state to interact (Kastritis and Bonvin, 2013a; Koshland, 1958). A subset of interactions which follow this model involve intrinsically disordered regions. Here an increase in order upon binding is associated with a decrease in entropy and results in weak, transient interactions (Perkins *et al.*, 2010). A third model, termed conformational selection, has been proposed. As proteins are dynamic in structure, each interaction partner will explore a number of conformational states, of which only particular states which will be able to interact (Kastritis and Bonvin, 2013a; Ma *et al.*, 1999; Bosshard, 2001; Boehr *et al.*, 2009).

Physicochemical Properties of Interaction Interface Regions

A number of features make important contributions to the properties of protein-protein interaction interfaces. These include the physicochemical properties of amino acids, such as charge and hydrophobicity, in addition to solvent accessibility, hydrogen bonds, secondary structural elements, steric properties (i.e., shape complementarity) and flexibility (Gromiha and Yugandhar, 2017; Keskin *et al.*, 2016). Protein interaction interfaces can be further divided into 280 core and rim regions (see Fig. 4). It has been shown that interface core regions, although surface exposed before binding, are enriched in hydrophobic residues and have amino acid compositions similar to the buried interior of a protein. In contrast, the rim regions differ less from other surface regions, and maintain a degree of solvent exposure upon binding. Hydrophilic and charged residues are usually enriched in such regions (Chakrabarti and Janin, 2002; Guharoy and Chakrabarti, 2005).

Fig. 3 Schematic showing protein mechanisms through which protein A (blue) recognises its binding partner, protein B (red): (a) lock and key, (b) induced fit, (c) conformational selection. Protein B can also undergo conformational changes, however here it is represented as a rigid body for simplicity. Adapted from Kastitis, P., Bonvin, A., 2013a. On the binding affinity of macromolecular interactions: Daring to ask why proteins interact. *J R Soc Interface* 10, 20120835. doi:10.1098/rsif.2012.0835.

Fig. 4 Schematic showing homodimeric thioredoxin interface (PDB:3zxx) – core (red) and rim regions (blue) can clearly be distinguished. Note the core is composed of hydrophobic amino acids and the rim is composed of hydrophilic amino acids. The localisation of the interface is depicted on the left side in a ribbon representation of the homodimeric complex (Reproduced from Campos-Acevedo, A.A., Rudino-Pinera, E., 2014. Crystallographic studies evidencing the high energy tolerance to disrupting the interface disulfide bond of thioredoxin 1 from white leg shrimp *Litopenaeus vannamei*. *Molecules* 19, 21113-21126. doi:10.3390/molecules191221113).

Distinctions also exist between the properties of obligate and transient interaction interfaces. Hydrophobic interactions make a larger contribution to obligate interfaces whereas transient interfaces rely more on the formation of salt bridges (Keskin *et al.*, 2016). Phosphorylation sites also frequently play a role in transient interactions (Keskin *et al.*, 2016). Obligate interactions have been coined hairy by Kufareva *et al.* (2007), who found such interactions to rely on amino acid side chains. This contrasts with their findings on transient interactions, where protein backbones were determined to play a greater role. Although rare, disulphide bonds have been shown to play an important role in stabilising a number small complexes (Acuner Ozbabacan *et al.*, 2011).

It has been shown that only a small number of residues make large contributions to the binding affinity of protein-protein interactions (Bogan and Thorn, 1998; Moreira *et al.*, 2007). These are termed hotspot residues and tend to cluster within the core of interfaces (Keskin *et al.*, 2005); furthermore, they have been shown to be shielded from bulk solvent by the side chains of neighbouring residues (Li and Liu, 2009). Such shielding residues have been termed the O-ring due to the shape they form around core residues. Arginine, tryptophan and tyrosine have been found to be both most enriched in hotspots and to account for the greatest proportion of hotspot residues (Bogan and Thorn, 1998).

Finally, it is important to note that solvent water molecules can play an important role in protein interactions, in particular as they can fill cavities in the interaction complex, and be involved in bridging hydrogen bonds (Janin, 1999).

Computational Approaches to Predicting Protein-Protein Interactions

In this section we overview different approaches used in the computational prediction of protein-protein interactions. We then focus techniques which add a three-dimensional structural element to the interaction network, namely computational interface prediction and protein-protein docking.

Overview

The computational prediction of protein-interactions can be approached in numerous ways and with multiple levels of granularity. At the coarsest level a binary prediction of whether two proteins interact can be performed. One factor to consider in evaluating the feasibility of an interaction *in vivo*, is the cellular compartment in which the interacting protein operate and their likely co-occurrence. A task of much finer granularity is the prediction of the exact atomistic nature of protein-protein interactions; this enables protein interaction interfaces to be inferred.

A recently developed database which exemplifies the use of multiple methods to predict protein-protein interactions is PrePPI (Garzon *et al.*, 2016). Approaches used by PrePPI are summarised in Table 3. For a more general review see Keskin *et al.* (2016).

Given the wealth of information which can already be obtained from PrePPI and other databases (e.g STRING (Szklarczyk *et al.*, 2015)), the rest of this article will focus on methods which enable the prediction of interaction interfaces (i.e. exactly which residues contact one another in a complex). This information has several important applications, for example in the rational design of drugs which target protein-protein interactions (Jin *et al.*, 2014; Mosca *et al.*, 2015; Duran-Frigola *et al.*, 2017; Kategaya *et al.*, 2017), and in the interpretation of genetic variants and expression data. Here 3D structural data can be used to assess the impact of a genetic variant on the binding affinity of an interaction, and thus its edgetic impact on the network. Variants which localise to a protein core may disrupt a protein's structure, effectively removing a node from the network, whereas those which localise to interaction interfaces may affect specific interactions (edges in the network) (Sahni *et al.*, 2015; Engin *et al.*, 2016; Yi *et al.*, 2017). Therefore residue level information describing protein interaction interfaces is essential for the edgetic modelling of disease-associated variants (Mosca *et al.*, 2015).

Protein-Protein Interface Prediction

Interface predictors make use of known features of protein-protein interactions interfaces, as outlined in Section Affinity Purification Coupled with Mass Spectrometry (AP-MS), in order to predict which residues are involved in such interfaces. A distinction must be made between partner-specific and non-partner-specific predictors. Partner-specific predictors

Table 3 Methods used by PrePPI in the prediction of protein-protein interactions

Method	Description
Molecular Modelling	From the structures or models of a complex A:B, A and B are superimposed onto experimentally determined structures of A' in complex with B'. Interaction probability is then evaluated based on structural properties of the modelled interface and structural similarity of A and B with their homologs.
Phylogenetic profile	If orthologs of A and B are frequently present in the same species they are deemed more likely to interact.
Gene ontology	If proteins A and B have similar functions they are deemed more likely to interact.
Orthology	If orthologs of A and B are known to interact in other species they are deemed likely to interact.
Expression profile	If A and B demonstrate similar expression profiles they are deemed likely to interact. This can be extended to the expression profiles of orthologs.
Partner redundancy	If protein A interacts with a number n of proteins which are structurally similar to B, the likelihood of B interacting with A increases with n.
Protein peptide	If A contains a peptide (sequence motif) known to interact with a particular domain type present in B, A and B are considered likely to interact.

Source: Garzon, J.I., Deng, L., Murray, D., Shapira, S., Petrey, D., Honig, B., 2016. A computational interactome and functional annotation for the human proteome. *eLife* 5. doi:10.7554/eLife.18715.

(e.g., PS-HomPPI (Xue *et al.*, 2011), EV-complex (Hopf *et al.*, 2014)) take as input two query proteins, A and B, which are known to interact, and predict which residues constitute their interaction interface. Non-partner specific predictors (e.g. NPS-HomPPI (Xue *et al.*, 2011), SPPIDER (Porollo and Meller, 2007)) take a single query protein, A, and predict the residues that are likely to be involved in interactions with any interaction partner.

The following sections outline different categories of interface predictors and representative methods for each category are summarised in Table 4.

Sequence-based predictors

Features which can be derived from sequence alone, such as the physicochemical properties of amino acids, hydrophobicity and interface propensity can be used to predict whether residues are involved in protein-protein interactions. Properties are generally calculated using a sliding window or subsequence of a certain number of residues (Xue *et al.*, 2011; Rydevik *et al.*, 1991; Ofra and Rost, 2003). Some sequence-based predictors, such as PSIVER (Murakami and Mizuguchi, 2010) and ISIS (Ofra and Rost, 2007) also use predicted structural information, including predicted SASA and secondary structure; this has been shown to improve their performance (Esmailbeiki *et al.*, 2016). SeRenDIP, a recently developed random forest based predictor, goes one step further by incorporating predicted dynamics (predicted backbone flexibility) in its predictions (Hou *et al.*, 2017).

As interface residues are more conserved than non-interface surface residues (as detailed in Section Homology and Conservation), evolutionary information derived from multiple sequence alignments can be used in the prediction of interface residues. A more sophisticated use of evolutionary information to predict protein interaction interfaces is used by co-evolutionary methods; these make use of the theory, outlined in Section Homology and Conservation, that compensatory mutations on opposing interfaces should be selected for during evolution. A key challenge in these methods has been distinguishing between the direct coupling of residues (as they are in direct contact) and indirect coupling of residues (residue A and B covary as they are both in contact with residue C). A number of approaches, which rely on the creation of a global statistical model, have been used to address this challenge. These include direct coupling analysis, protein sparse inverse covariance and Bayesian network-based approaches (de Juan *et al.*, 2013).

Sequence-based methods are generally less accurate than structure-based methods, but are able to obtain a much greater coverage of the proteome due to the higher availability of sequence information (Gallet *et al.*, 2000). Coevolutionary methods have improved dramatically over recent years (Esmailbeiki *et al.*, 2016), but are limited to predicting interfaces where both partners are known, and a large number of homologous sequences are available. This is often a hindrance when protein partners are exclusive to a particular taxonomic branch (Hopf *et al.*, 2014).

Structure-based predictors

A number of predictors use structural features, such as solvent accessible surface area (SASA), secondary structure, geometry and B-factor, directly (Esmailbeiki *et al.*, 2016; Porollo and Meller, 2007). The performance of predictors which already use sequence-based features is greatly improved by this; particularly as, through the use of SASA, buried residues in the protein core can be immediately ruled out (Xue *et al.*, 2011). Other methods map features on to the protein structure and search for 3D patches of residues whose properties are consistent with being involved in protein-protein interaction interfaces (Porollo and Meller, 2007) (this can be seen as a 3D version of the sliding window approach outlined in Section Sequence-Based Predictors). Although not specific to protein interaction interfaces, ConSurf notably uses this method to facilitate the identification of functional sites (Ashkenazy *et al.*, 2010).

Partner specific structural predictors can take into consideration features of both structures, for example shape complementarity and electrostatics of the interface regions. Such predictions are thought to be more reliable if binding follows the lock and key model (see Section Physicochemical Properties of Interaction Interface Regions) as shape complementarity of unbound structures will be less complete if binding follows the induced fit model (Xue *et al.*, 2011). Furthermore, this strategy is most successful if available monomeric structures are similar in conformation to that in which the partners bind.

Template-based predictors of interfaces search for homologous proteins in structurally resolved complexes. Here the homologous complex may involve homologs of both proteins A and B, or it may only involve a homolog of one of the interaction partners. In the case that only one interacting partner is involved, the observation that proteins often use the same interface to interact with different partners, as outlined in Section Homology and Conservation, can be used to make a less confident prediction of the interaction interface. Where homologous complexes for partner specific interactions are available, these methods tend to give the best results. As outlined in Section Protein Domains, interactions may only occur between specific domains of two interacting proteins. Therefore, where no global templates are available to model an interaction, templates which are homologous at the domain level, if available, can be used; this is the approach which has been taken by Interac-tome3D (Mosca *et al.*, 2013), which uses the 3DID database (Mosca *et al.*, 2014) as a resource to identify interacting domain-domain templates. Some methods, such as HomPPI (Xue *et al.*, 2011), incorporate information from multiple structural templates, where available, in order to improve performance.

Structural neighbourhood methods also use template-based prediction methods. For these methods the protein of interest must have an experimental structure, despite the absence of a structure where it is present with its interaction partner. Here, rather than homologs, templates are searched for where the sub-units are structurally similar to the query protein. Methods such as PredUs (Zhang *et al.*, 2011) use global similarity of the query structure to the template whereas PrISE (Jordan *et al.*, 2012) also takes interface similarity specifically into account.

Combining features and methods

Information from different features can be combined to make predictions in multiple ways. Empirical scoring functions can be used; however, these functions can suffer if knowledge of the system (in this case the parameters which determine whether proteins interact) is incomplete. Such scoring functions have the disadvantage that their form must be predetermined and are generally linear in structure. Machine learning techniques have the advantage that they can make use of non-linear combinations of features and can, to a greater degree, infer their functional form from the data (Woźniakowski *et al.*, 2017). A number of different algorithms including Support Vector Machines (SVMs) (Sriwastava *et al.*, 2015; Zhao and Gong, 2017), neural networks (Porollo and Meller, 2007) and random forests (Hou *et al.*, 2017) can be used to classify residues as interacting or non-interacting. Researchers are beginning to explore the application of deep learning methods to the prediction of protein-protein interaction interfaces (Zhao and Gong, 2017), however these techniques require vast amounts of training data.

A number of methods, for predicting protein interaction interfaces, incorporate several distinct steps. For example, PRISM (Baspinar *et al.*, 2014), although primarily a template based method, guides structural alignments through the evolutionary prediction of hotspot residues. Succeeding structural alignment, further docking (see Section Docking for more information) and refinement steps are performed.

As more predictors become available, their results can be used as features to train meta-predictors, which generally achieve better performance than each individual predictor (Qin and Zhou, 2007; de Vries and Bonvin, 2011). Here, care must be taken that testing data used to evaluate the meta predictor does not overlap with the training data of its component predictors.

Docking

Given two protomers or proteins with structures, docking is a computational method to predict 3D structural protein-protein interaction complexes of target proteins (Rodrigues and Bonvin, 2014). It has evolved rapidly in parallel to the increase of publicly available molecular structures (Soni and Madhusudhan, 2017) and advances in computational technology (Schlick *et al.*, 2011). The Critical Assessment of Predicted Interactions (CAPRI) (Janin, 2005) is dedicated to the evaluation of protein-protein docking and organised by the research community to target unpublished crystal or NMR structural complexes. It has encouraged participations from different institutes worldwide and has become an important event in the field of protein structure prediction. Several representative computational tools and participants are listed in Table 5.

The key elements of docking are 3D structures (experimental or modelled) of target proteins, a sampling procedure to generate the conformational landscape of the predicted structural interactions, and a scoring function to compare and assess the predicted models (Rodrigues and Bonvin, 2014). Mainly, three types of scoring functions are used to evaluate binding affinity of protein interaction models: force-field scoring (calculating van der Waals (VDW) energy, electrostatic energy and bond stretching/bending/torsional forces); empirical scoring (integrating different weighted energy scores selectively to fit empirical binding data; and knowledge-based scoring (calculating statistical potential of the protein complex based on experimentally solved atomic structures) (Huang *et al.*, 2010). However, sampling and scoring are still challenging because of the incomplete quantitative information available regarding the impact of conformational change and molecular flexibility on binding affinity, as well as difficulties associated with certain protein types (e.g. lipid or membrane binding proteins) and multi-component assemblies (Kastritis and

Bonvin, 2013b).

A Step by Step Guide to the Prediction of Three-Dimensional Protein-Protein Interactions

Here we outline how methods and resources, introduced throughout this article, can be applied to a query, consisting of two proteins (A and B), in order to obtain a 3D binary interaction complex model. Proposed steps are outlined below and illustrated in Fig. 5.

- 1) Given proteins A and B, for which we want to predict interactions, search PPI databases with structural annotations (e.g., Interactome3D (Mosca *et al.*, 2013), PrePPI (Garzon *et al.*, 2016)) and identify whether there are available models.
- 2) If there are predicted models of the complex, we can evaluate them as described in point 5) below.
- 3) If no models are available, different approaches can be applied. Models can be built using information derived from sequence based predictors and/or structure-based predictors. See Section Protein-Protein Interface Prediction and Table 4.
- 4) Apply docking or other refinement methods in order to improve predictions. See Sections Combining Features and Methods and Docking.
- 5) Evaluate models based on some quality measurement of prediction methods or scoring functions described in Docking. In addition, general protein structure assessment tools can be applied such as MolProbity (Chen *et al.*, 2010) or QMEAN (Benkert *et al.*, 2008).
- 6) Re-apply prediction methods if the qualities are not satisfied. Make use of other listed approaches, these can be applied and adapted to improve PPI model predictions.

Future Directions

This article has focussed on the prediction of binary interaction complexes, and more specifically on the prediction of protein-protein interfaces. However most biological complexes that play a crucial functional role in the cell, are made up of multiple protein components. Template based methods can be used to model such assemblies, but these are limited by the lack of available

Fig. 6 A kaleidoscopic schematic for protein-protein interaction prediction.

experimentally resolved multicomponent structures. These are still particularly challenging to address by modern techniques. Notably, recent advances in the cryo-EM methodology allow for the structural determination of large complexes at near atomic resolution (Chlanda and Krijnse Locker, 2017; Orlov *et al.*, 2017; Lengyel *et al.*, 2014). Additionally, this technique can be complemented by data from crystallography and NMR experiments, as smaller complexes or single component structures can be projected onto EM density maps and help in the accurate reconstruction of a complex. In light of this, the PDB has launched a prototype framework for depositing hybrid models which result from a combination of experimental techniques (Burley *et al.*, 2017). This will allow for efficient use of integrated data in prediction methods.

A challenge will be in the extension and development of predictors to make efficient use of available multimeric information and the associated level of resolution. The Swiss-Model developers have started to address this quest with the release of a new pipeline, which enables the automated modelling of oligomeric complexes (Bertoni *et al.*, 2017). In parallel, a handful of docking programs are starting to address the automated docking of multiple components, although the procedures still rely mainly the pairwise docking of all the complex components (Soni and Madhusudhan, 2017).

As more experimental data are released, it becomes imperative to incorporate these into both computational predictors and docking methods. A number of computational procedures are already being developed to accomplish the efficient merging of restraints from data derived from different sources (this data may be varied in both nature and accuracy) (Politis and Schmidt, 2017; Schmidt *et al.*, 2017; Tamo *et al.*, 2017). Low resolution data, for example from small angle x-ray scattering (SAXS), EM, Ion Mobility Mass Spectrometry, and even data from site-directed mutagenesis experiments, can provide a conditional universe in which predictions can take place. One example which uses this approach is the docking software HADDOCK (Rodrigues and Bonvin, 2014), which already allows the integration of data from multiple sources, in the form of restraints.

Throughout this article we have seen how kaleidoscopic snapshots of the protein interaction universe (Fig. 6) can be expanded and integrated through the use of computational methods. However, only through the continued development and integration of both experimental and computational methods, it is conceivable that we may one day achieve a complete and accurate multi-dimensional map of the protein interaction landscape.

Protein–Protein Interaction Databases

Ashwini Patil, The University of Tokyo, Tokyo, Japan

Introduction

The function of a protein in a cell depends on its interaction partners in the form of other proteins, nucleic acids and small molecules. These interactions change with time and cellular state allowing proteins to perform their functions. The knowledge of these interactions can be used to make interaction networks that can be analyzed to identify functional modules of proteins and their interconnections to ultimately understand cellular function (Cafarelli *et al.*, 2017). The identification of protein-protein interactions (PPIs) is thus an important means of understanding biological processes.

The detection of interactions between proteins began on a large scale in the early 2000s, prior to which PPIs were identified mainly as those between proteins of interest or those associated with a specific pathway or function. Starting in the year 2000, several studies reported a large number of protein-protein interactions identified using high-throughput screening methods (Uetz *et al.*, 2000; Ito *et al.*, 2001; Ho *et al.*, 2002; Giot *et al.*, 2003; Li *et al.*, 2004; Rual *et al.*, 2005; Stelzl *et al.*, 2005). Over the years, the number of interaction datasets has increased exponentially. This lead to the need for resources that would combine the large number of interactions, annotate them and make them interoperable. This need is fulfilled by PPI databases which organize, curate, integrate and annotate PPI data and make it available for downstream analysis.

All PPI databases collect protein-protein interactions either directly from literature, through direct deposition by authors, or from other databases. Databases use different criteria to filter, annotate and group the collected interactions and provide distinct user interfaces to allow users to access the PPI data. In some cases, methods to analyze this data are also provided. Some databases are limited to one or a few species. An important service provided by the databases is the assessment of the PPIs for reliability. It is known that PPIs identified in-vitro by existing methods have a large number of false-positives i.e. interactions that show incorrect binding or are not observed in-vivo (Von Mering *et al.*, 2002). This is now changing with increasing confirmation of the identified interactions using validation assays (Luck *et al.*, 2017). However, several databases now assign scores to interactions that help users identify those interactions that are more likely to exist in the cell. Due to limitations of interaction detection techniques, the number of interactions experimentally identified is much smaller than those existing in the cell. Therefore, a few databases also provide predicted PPIs, either as predicted interactions between proteins or functional associations identified by genetic interactions.

Thus, there is a wide variety of PPI databases available. As the number of PPIs detected increases and the databases become more specialized, it is becoming increasingly difficult to keep abreast of the various databases and their offerings. Therefore, it is important for users to understand these databases to help identify the ones that will be most appropriate in a specific study. This article provides an overview of the current major PPI databases. The article first describes the different types of interactions identified and stored in PPI databases. This is followed by a brief description of several databases, their special features and the methods they use for PPI quality assessment. Next, a description of the recent development of community-wide standards and protocols that make it easier to access database content for in-depth analyses is provided. Finally, a discussion of the strengths and weaknesses of the current PPI databases is presented and suggestions are made for their improvement.

Types of Interactions

PPIs can be broadly classified into two groups – direct or physical, and indirect or non-physical interactions. These are further divided into sub-groups (Table 1). These groups are frequently used to classify PPIs in databases.

Physical Interactions

Physical interactions are those in which the interactors physically bind to each other. These may be interactions between proteins or proteins and other molecules. Physical protein-protein interactions can further be divided into two categories depending on the type of method used to identify them. Binary interactions are direct binding events that are detected between two proteins. Several

Table 1 Classification of interactions in PPI databases

Class	Definition
Physical/direct	Direct binding event between two proteins
Non-physical/Indirect	Functional association – genetic or predicted interaction
Small-scale	Detected in small experiment with 100 or less interactions
High-throughput	Detected in proteome-scale experiment
Binary	Interaction between two proteins
Complex	Association of multiple proteins; direct interactions unknown

methods can be used to detect binary interactions, such as, yeast two hybrid (Y2H) systems (Ito *et al.*, 2001; Giot *et al.*, 2003; Li *et al.*, 2004; Rolland *et al.*, 2014), protein arrays (Yazaki *et al.*, 2016), fluorescence resonance energy transfer (FRET), and structure determination methods like X-ray crystallography and NMR Spectroscopy. PPIs can also be identified in the form of protein complexes, or associations, using methods like affinity purification followed by mass spectroscopy (AP-MS) (Hein *et al.*, 2015; Huttlin *et al.*, 2015, 2017) and co-fractionation followed by mass spectroscopy (CoFrac-MS) (Wan *et al.*, 2015). Of these methods, Y2H, AP-MS and CoFrac-MS are amenable to high-throughput experiments and have been used to identify PPIs on the proteomic scale. Methods identifying protein complexes do not provide information about direct binding events in the complex. Hence binary interactions are often predicted from protein complex data before they are stored in databases. Databases use one of two models to convert protein complex data into binary interactions – spoke model or matrix model (Bader and Hogue, 2002). The spoke model assumes that the bait protein, i.e. the protein that is tagged and used to elute other proteins that associate with it, directly binds to all the other associated proteins. The matrix model assumes that all proteins eluted together interact with each other. The spoke model is more conservative and results in fewer false positive interactions (Bader and Hogue, 2002) and hence, is the model of choice in several databases. However, neither model gives the true binding states, often resulting in the prediction of incorrect binary interactions.

An additional classification that is common for PPIs is that based on the size of the experiment in which they are detected. PPIs that are detected in small, focused studies, typically identifying less than 100 interactions, are often denoted as small-scale (Patil *et al.*, 2011). On the other hand, interactions identified in proteome-wide studies are deemed as high-throughput. The cutoff interaction count separating small-scale from high-throughput experiments varies with databases. It has long been argued that interactions identified in high-throughput experiments have larger number of false positives or non-physiological interactions (Von Mering *et al.*, 2002; Wodak *et al.*, 2013). This makes scoring interactions for reliability very important. It has also been observed that interactions from the same species identified by different methods are complementary and have very little overlap (Von Mering *et al.*, 2002; Wodak *et al.*, 2013). It has been proposed that this may be the result of the large number of potential interactions in the cell all of which cannot be identified by a single method, and the low sensitivity of the methods, rather than the high rate of false interactions identified by these methods (Wodak *et al.*, 2013; Luck *et al.*, 2017).

Non-Physical Interactions

Indirect or non-physical interactions are functional associations between proteins and/or other molecules that may or may not be direct binding events. Indirect associations of proteins may be identified as genetic interactions using synthetic lethal arrays (Costanzo *et al.*, 2010). They can also be predicted interactions or associations (Skrabaneck *et al.*, 2008). Sequence homology is often used to predict protein associations such that homologs of interacting proteins in the same or different species are also predicted to interact. This is a method that is often used to transfer interactions between closely related species. For example, interactions identified in mouse can be transferred to human through orthologous proteins (Brown and Jurisica, 2005). Structural methods can also be used to predict PPIs through binding surface prediction and docking of two proteins with known structures (Mosca *et al.*, 2013). Genomic context approaches are another commonly used method of PPI prediction. These include methods based on (1) identifying pairs of genes that are in close proximity or fused in a few species, (2) the coordinated presence or absence of genes in different genomes and, the presence of conserved regions and (3) correlated mutations in two protein/gene sequences indicating a possible role in binding (Skrabaneck *et al.*, 2008). Finally, co-occurring terms in scientific abstracts obtained through text-mining can also be used to predict functional associations between proteins (Papanikolaou *et al.*, 2015).

Protein–Protein Interaction Databases

Protein-protein interaction databases are divided into two categories: (1) primary databases, and (2) derived or consolidated databases.

Primary Databases

Primary databases collect and store interactions directly from literature or through author submissions (Table 2). They may contain data from small-scale focused studies or large-scale high-throughput experiments. Following are some of the major primary databases storing PPI data:

1. IntAct: A database containing molecular interactions curated from literature or obtained by direct submission from authors (Orchard *et al.*, 2014). Most of the interactions in IntAct are physical associations from high-throughput experiments, and the species with the highest representation is human. It is one of the few PPI databases with extensive annotations and proteins mapped to multiple database identifiers.
2. BioGRID: A primary database that collects interactions from literature, mainly from high-throughput experiments, and stores them after curation (Chatr-Aryamontri *et al.*, 2017). The interactions in BioGRID are classified into physical or genetic interactions. BioGRID also stores data about post-translational modifications in proteins. It contains the largest number of curated interactions in yeast. All interactions in BioGRID are in binary format i.e. complex associations have been converted to binary format using the spoke model in which the bait protein interacts with each prey protein.

Table 2 Primary protein-protein interaction databases

Database	Interactions	PPI type	Associations	Scoring	Focus	Reference
IntAct	Protein-molecule	Experimental	All	Yes	All	Orchard et al. (2014)
BioGRID	Protein-molecule	Experimental	All	No	All	Chatr-Aryamontri et al. (2017)
MINT	Protein-molecule	Experimental	All	Yes	All	Ceol et al. (2010)
DIP	Protein-protein	Experimental	All	No	All	Salwinski et al. (2004)
HPRD	Protein-protein	Experimental	Physical	No	Human	Prasad et al. (2009)
MatrixDB	Protein-protein	Experimental	All	No	All	Launay et al. (2015)
CORUM	Protein-protein	Experimental	Physical	No	Mammals	Ruepp et al. (2010)
MIPS	Protein-protein	Experimental	Physical	No	Mammals	Pagel et al. (2005)

Interactions: Protein-protein – interactions exclusively between proteins; Protein-molecule – interactions between proteins and proteins, DNA, RNA, drugs or other small molecules.

PPI type: Experimental – experimentally identified interactions; Predicted – predicted associations.

Associations: All – physical and indirect associations between interactors; Physical – only interactions involving physical binding.

Scoring: Presence of confidence score assessing interaction reliability.

Focus: Specific area of focus of the database eg. Species or biological process specific.

3. MINT: MINT collects and curates PPI data on a smaller scale than IntAct and BioGRID ([Ceol et al., 2010](#)). This data is now hosted by the IntAct database. However, MINT still contains some interactions that have not been transferred to IntAct.
4. DIP: DIP is a much smaller database compared to IntAct and BioGRID. It stores curated protein-protein interactions from literature ([Salwinski et al., 2004](#)).
5. HPRD: The Human Protein Reference Database (HPRD) is one of the most comprehensive resources of physical protein-protein interactions in humans ([Prasad et al., 2009](#)). The data is manually curated from literature, primarily from small-scale experiments. Interactions in HPRD are in binary format and come with isoform information. HPRD data available for download is not as detailed as that provided by some of the other primary databases.
6. MatrixDB: This is a database that curates and stores interactions of extracellular matrix proteins obtained from literature ([Launay et al., 2015](#)).
7. CORUM: A database containing manually annotated protein complexes from mammals. This database contains small-scale interactions collected and manually curated from literature ([Ruepp et al., 2010](#)). These interactions are taken only from small-scale focused experiments and are, therefore, considered to be more reliable than those present in larger databases which contain a greater number of interactions from high-throughput experiments. The data from CORUM is also frequently used as a gold standard, or known true, dataset in PPI quality evaluation.
8. MIPS: MIPS is a database of manually curated protein-protein interactions in mammals from literature ([Pagel et al., 2005](#)). MIPS is also used as a gold standard dataset for binary protein-protein interactions.

Primary databases perform a commendable task of collecting, curating and making the PPI data available. But several issues need to be addressed. At present, PPI data is distributed across multiple primary databases. As a result, getting a complete set of interactions for network or pathway analysis requires combining data from multiple sources. The adoption of standards by several primary databases has significantly eased this process. However, combining data from multiple databases and annotating them is still non-trivial for two reasons. Firstly, databases use different interactor identifiers requiring the mapping of identifiers from multiple databases onto a common identifier before merging. Secondly, the presence of interactions using obsolete or incorrect identifiers makes merging challenging. The depth of curation of data varies with each database. Thirdly, some databases are better curated and have more annotations than others. As a result, integrating information from databases requires time and resources, and derived or consolidated databases help resolve these issues.

Derived Databases

Derived databases take PPI data from primary interaction databases, integrate it, filter it and annotate it ([Table 3](#)). Many of the derived databases also provide an additional level of curation. The derived databases try to alleviate the problems users face during integration of multiple PPI datasets by mapping all the interactor identifiers from multiple databases to a common identifier followed by combining the interactions into a unique set. After integration, interactions may be selected by the databases for one or more species or a specific biological system. Along with integration and selection, several databases also provide confidence scores to assess the quality of the interactions. Some databases also provide predicted interactions and interactions with annotations of 3D structure. As a result, derived databases are often the ones from which users get their interaction data for further analysis. Following are some of the major derived PPI databases.

1. STRING: STRING is a database of functional associations ([Szklarczyk et al., 2015](#)). It is one of the largest derived databases. It collects physical and indirect PPIs from multiple primary databases. It also contains predicted functional associations between proteins. All interactions in STRING are scored using multiple evidences for their reliability. The data from STRING is now available for network analysis through a plugin in the software, Cytoscape ([Cline et al., 2007](#)).

Table 3 Derived protein-protein interaction databases. Column descriptions are same as those in **Table 2**

Database	Interactions	PPI type	Associations	Scoring	Focus	References
STRING	Molecular	Experimental + Predicted	All	Yes	All	Szklarczyk <i>et al.</i> (2015)
HitPredict	Proteins	Experimental	Physical	Yes	All	Lopez <i>et al.</i> (2015)
iRefWeb	Proteins	Experimental	All	Yes	All	Turner <i>et al.</i> (2010)
mentha	Proteins	Experimental	Physical	Yes	All	Calderone <i>et al.</i> (2013)
InnateDB	Molecular	Experimental + Predicted	All	No	Mammals (immunity)	Breuer <i>et al.</i> (2013)
IID	Proteins	Experimental + Predicted	All	No	6 organisms	Kotlyar <i>et al.</i> (2016)
HPIDB	Proteins	Experimental + Predicted	All	No	Human	Ammari <i>et al.</i> (2016)
ConsensusPathDB	Molecular	Experimental	All	No	3 organisms	Kamburov <i>et al.</i> (2013)
HAPPI	Proteins	Experimental + Predicted	All	Yes	Human	Chen <i>et al.</i> (2017)
HIPPIE	Proteins	Experimental	All	Yes	Human	Alanis-Lobato <i>et al.</i> (2017)
DroID	Molecular	Experimental + Predicted	All	Yes	<i>Drosophila</i>	Murali <i>et al.</i> (2011)
Interactome3D	Proteins	Experimental	Physical	No	All (3D structure)	Mosca <i>et al.</i> (2013)

- HitPredict: HitPredict is a derived database that includes physical protein-protein interactions from multiple primary databases (Lopez *et al.*, 2015). HitPredict is a deeply curated database using several automatic and manual checks to assess the quality of the PPI data from primary sources. Extensive checks are performed to confirm the validity of the interacting proteins and significant effort is put into assigning the correct identifier to proteins. Interactions of proteins that do not map to valid identifiers, are not in the same species, or that do not have valid experimental annotations are not included. HitPredict includes interactions from organisms that have at least 10 high-quality interactions. HitPredict also provides a reliability score for PPIs.
- iRefWeb: This is a derived database that integrates PPI data from multiple sources (Turner *et al.*, 2010). It includes physical as well as indirect interactions. iRefWeb provides detailed information about each interaction in the form of the number of primary databases it was obtained from and the annotation of the interaction in each source database. It also provides extensive mapping to multiple protein and gene identifiers including the various isoforms. iRefWeb provides a reliability score for each interaction.
- mentha: This is a derived database that automatically collects and integrates data published by multiple primary databases using a web service (Calderone *et al.*, 2013). mentha depends on the source databases to provide the curation and the correct interactor identifiers. mentha also provides a reliability score. It provides some network analysis tools to extract subnetworks of genes and identify the possible paths between two set of genes.
- InnateDB: InnateDB is a database of associations between mammalian genes and proteins that are specific to the innate immune response (Breuer *et al.*, 2013). Interactions are limited to those in human, cow and mouse. It includes a small set of curated interactions, a set of interactions validated from publications and a set of predicted interactions. Interactions are physical as well as indirect associations between proteins, DNA and RNA. InnateDB provides tools for pathway, gene ontology and network analyses. The interactions in InnateDB are not scored.
- IID: The Integrated Interaction Database combines experimentally identified interactions from primary databases and includes predicted PPIs in yeast, worm, fly, rat, mouse and human (Kotlyar *et al.*, 2016). It also provides tissue specific PPIs. IID does not provide reliability scoring for interactions.
- HPIDB: HPIDB provides interactions between proteins from pathogens and their host organisms (Ammari *et al.*, 2016). PPIs are collected from primary and some derived databases without reliability scoring.
- ConsensusPathDB: Physical and indirect interactions from human, yeast and mouse are collected from primary sources and curated (Kamburov *et al.*, 2013). Network analysis and gene set enrichment analysis is provided. This database also includes information about protein-drug interactions. A confidence score is provided for each interaction.
- HAPPI: HAPPI is a database of experimentally identified and predicted human protein-protein interactions collected from primary databases (Chen *et al.*, 2017). All interactions are curated and scored.
- HIPPIE: A human protein-protein interaction database with confidence scoring and network analysis tools (Alanis-Lobato *et al.*, 2017). Interactions are collected from multiple PPI databases.
- DroID: A database of physical and genetic interactions between proteins, DNA and RNA from the fly, *Drosophila melanogaster* (Murali *et al.*, 2011). It provides extensive links to fly specific databases such as FlyBase (Gramates *et al.*, 2017). It also includes normalized gene expression values and expression correlation values. Orthologous interactions predicted from known human, worm and yeast interactions are also part of this database.
- Interactome3D: A derived database that collects PPIs from primary source databases and provides 3D structural annotations to the interacting proteins (Mosca *et al.*, 2013). 3D structures are predicted for the complete or partial protein complex, when unknown, along with the binding mode.

Quality Assessment and Scoring

Most of the experimentally identified PPIs in databases are detected using high-throughput experimental methods on a proteome-wide scale and potentially contain spurious interactions (Von Mering *et al.*, 2002; Wodak *et al.*, 2013). In spite of the increasing

accuracy of these methods, assessing the existing interaction data for reliability is important before its use in downstream analyses. As described earlier, several PPI databases now provide a reliability score for the interactions that they contain.

Experimentally detected interactions can be scored in two ways. Firstly, they can be experimentally verified either by confirming a small set of the identified interactions or by assessing the accuracy of the experimental method to estimate the fraction of high-confidence interactions among those detected (Luck *et al.*, 2017). With the increase in experimental validation and assessment, most primary and derived databases provide information about author assigned confidence for interactions and experimental datasets. Secondly, interactions can be assessed computationally to identify the probability of the association or interaction being true and occurring in the cell.

The accuracy of the interaction detected is calculated using information about the type of association detected (physical or indirect), the method used to detect the interaction (Y2H, AP-MS), the type of experiment (small-scale or high-throughput) and the number of publications that support the interaction. Several databases including IntAct, MINT, mentha, HAPPI, HIPPIE and HitPredict incorporate these experimental details into the reliability score they calculate.

To assess the probability of an interaction occurring *in vivo*, the features of the interacting proteins or the presence of homologous interactions may be used. HitPredict uses three characteristics to calculate an annotation score for an interaction – the presence of a homologous interaction, the same gene ontology terms associated with the interacting proteins and the presence of domains that are observed to interact in 3D structural data in the interacting proteins (Patil and Nakamura, 2005). The annotation score is combined with the experiment score, calculated using information about the experimental method, to give the final confidence score in HitPredict (Lopez *et al.*, 2015). STRING calculates the probability of two random pairs of proteins binding and includes a score based on homology and co-occurrence to calculate the final score (Szklarczyk *et al.*, 2015). The reliability score in mentha is based on the number of publications supporting an interaction and the type of method used to detect the method (Calderone *et al.*, 2013). ConsensusPathDB integrates interaction assessment scores calculated using graph-based topology, literature evidence, pathway co-occurrence of the interacting proteins and the functional term similarities (Kamburov *et al.*, 2013). iRefWeb calculates the reliability score using the number of publications supporting the interaction, the method used to identify the interaction and the presence of the same interaction in other species (Turner *et al.*, 2010). HIPPIE uses a semi-automated scoring procedure based on experimental evidence of the interaction (Alanis-Lobato *et al.*, 2017). HAPPI uses a combination of heuristic scores for the source and detection method to calculate a final score (Chen *et al.*, 2017).

With each database adopting a different method to assess the interaction quality, it is not surprising that the high-confidence interactions identified by each database are different (Wodak *et al.*, 2013). Another reason for differences in the interactions deemed as high-confidence between databases is the different gold standard interactions that are used by these methods to evaluate their performance and set a threshold score that differentiates between the high and low confidence interactions. The gold standard datasets can be often biased and error-prone and tend to sometimes result in incorrect threshold scores. Therefore, it must be noted that while interaction scores are important for assessing the quality of interactions, they must be checked across multiple databases for the interactions of interest and used with caution when filtering interactions.

Community Standards

Given the large number of PPI databases and the increasing number of interactions in these databases, inter-operability is an issue that needs to be addressed. With each database having its own data model, terminology, filtering and curation criteria, combining data from multiple databases and mapping the proteins to common identifiers has become tedious and time-consuming. Community standards have been introduced by the Human Proteome Organisation Proteomics Standards Initiative – Molecular Interactions (HUPO PSI-MI) to address this issue (Orchard and Hermjakob, 2008).

PSI-MI has developed common data formats for sharing interaction data in the form of XML (PSI-MI XML) and tab-delimited (MITAB) files. Controlled vocabulary has been developed to describe interaction properties such as the molecular features of the interactors (protein, DNA, etc.), the type of interaction (direct, genetic, etc.) and the interaction detection method (biophysical, biochemical, etc.). The controlled vocabulary includes a standardized term to describe the interaction feature and an accession number that can be used to programmatically search and filter interactions based on their features (Orchard, 2012). HUPO PSI-MI also provides a standardized method for calculating the interaction score in the form of a PSIScore (Villaveces *et al.*, 2015). Most of the databases now provide downloadable files in these file formats and several follow the use of controlled vocabularies.

It is also possible to programmatically access the data within PPI databases so that it can be combined and analyzed. The PSI Common Query InterfaCe (PSICQUIC) is a query interface that allows users to programmatically access interaction databases and get data in PSI-MI XML or MITAB formats (Orchard, 2012). Depending on the database compliance, PSICQUIC also allows users to query for proteins using multiple identifiers. The user can query the most recent version of multiple databases that provide this web service. The PSICQUIC View at EMBL-EBI provides information about the databases that implement this service and their current status. Some databases like IntAct, BioGrid, MINT DIP, InnateDB, STRING and mentha are available through PSICQUIC.

Along with the definition of standardized formats and the availability of a standardized query interface, it is also important to specify common standards for data quality and curation. The International Molecular Exchange (IMEx) consortium has established common curation rules for PPI data. IntAct, MINT, DIP, MatrixDB and InnateDB are some of the members of the consortium. Member databases are committed to curating the data from published papers through a central database and web service, IMEx Central. The data is curated to standards specified by the IMEx consortium. Data curation is divided between the

members of the consortium to prevent overlapping curation efforts. The IMEx consortium provides users with a non-redundant set of interactions through the PSICQUIC service (Orchard *et al.*, 2012).

Future Directions

With the improvement in interaction detection technology and the rapidly increasing number of PPIs being detected, the role of databases in collecting, organizing and curating these interactions has become crucial. The existing PPI databases are doing an excellent job of making the interactions available to the scientific community. The established standards and web services have eased the access to interactions and their integration for downstream network analyses. It has now become possible to perform large-scale network analysis studies and to combine other omics and disease-related data in the context of the network to identify activated cellular pathways and novel functions of proteins.

Some problems associated with the data in PPI databases are the result of the properties of the techniques used to identify these interactions. For instance, there is a known functional bias in the interaction data as a result of the techniques used to detect the PPIs (Yu *et al.*, 2008). For example, Y2H data is enriched in interactions involving signal transduction while AP-MS interactions are enriched for proteins functioning in translation. This may be the result of Y2H being more suited to identify transient interactions while AP-MS being better for the identification of protein complexes. Current high-throughput methods also provide no information about the affinity of interactions, protein abundance, post-translational modifications of the proteins, tissue-specific expression patterns of genes, and the isoform participating in the interaction. All these are important properties of proteins and are known to impact the interaction landscape in the cell.

An estimate of the size of interaction universe in organisms shows that many new PPIs are yet to be discovered (Vidal and Fields, 2014). As the amount of protein-protein interaction data increases and the quality of these interactions improves, resources have to evolve to keep up with these changes. Therefore, existing databases will have to scale and improve their integration, curation and annotation methods. Firstly, integrating interaction data with other omics data needs to become easier through the use of extensive cross-referencing and identifier mapping by all databases. Secondly, the depth of curation needs to be improved in primary as well as derived databases. Obsolete identifiers, incorrect methods, interaction types, evidence types and other annotations are some of the errors that can creep into PPI data. Automatic, or semi-automatic, methods are necessary to correct these errors and reduce the task of manual curators. The scoring schemes used by different databases can also lead to different high confidence datasets and hence, greater uniformity in scoring of interactions is recommended. Finally, methods to analyze and visualize the interaction information are also important and need to be integrated into the databases. Basic network analyses and function enrichment analyses methods will dramatically increase the utility of PPI databases.

Despite these shortcomings, protein-protein interaction databases are critical for the future of large-scale biological data analyses. The next several years will be important as these databases develop new methods to deal with the large amount of data being generated as they make it easily accessible and available for analysis.

Computational Approaches for Modeling Signal Transduction Networks

Zhongming Zhao, The University of Texas Health Science Center at Houston, Houston, TX, United States

Junfeng Xia, Anhui University, Hefei, China

© 2019 Elsevier Inc. All rights reserved.

Introduction

Signal transduction is an essential biological process in cellular systems. It involves numerous biological functions in cell, and its disruption may lead to various diseases, phenotypes and drug treatment outcomes. Through dynamic and refined signal transduction, molecules connect and interact in a predefined fashion in signaling pathways so that the living organisms fulfill overall function in a harmonious way. Aberrant signal transduction in the pathways may cause dysregulation of biological processes, resulting in diseases such as cancer (Sever and Brugge, 2015). This article first introduces the basic concept about the signaling transduction, biological pathways, and molecular networks. Then, we describe the signaling transduction networks (STNs) in complex diseases by using cancer and its mitogen-activated protein kinase (MAPK) pathway as a specific example. MAPK pathway plays critical roles in multiple processes associated with many types of cancer and other diseases. Next, we introduce essential structural motifs in STNs, including feedback and feed forward loops. Finally, we review the databases and analysis tools that have been used in STNs and highlight some applications of computational modeling of STNs to complex disease studies.

Basic Concept in Signal Transduction Networks

Complex cellular activities such as cell growth and division, cell death, cell fate, and cell motility are generally regulated through the refined response of cells to stimuli in their environment. The transportation of an extracellular cue through cell membrane to the nucleus and intracellular signal passing between organelles or from organelles to other cellular components in response to cell stress or metabolic status are all referred to signal transduction (Liu *et al.*, 2008). Signal transduction allows cells to respond to the cues from either neighboring cells or even distant cells and to change their behavior accordingly. Cells constantly and concordantly receive a variety of signals that will affect one or multiple intersections within a signaling transduction pathway, as well as multiple signaling transduction pathways. Although numerous cell signaling transduction events and related molecular mechanisms have been uncovered, a deep understanding of cellular signaling transduction has still remained a main challenge in biological and biomedical research. This is mainly because there are thousands of small molecules, often with different forms or isoforms, that interact in a dynamic and complex fashion (e.g., spatiotemporal dimensions). Such a complex, dynamic feature is a major limit to apply the currently available statistical or computational modeling. However, deep deciphering of the complexity of cell signaling is ultimately essential for investigators to understand the normal biological functions as well as the pathophysiology of diseases. Such knowledge builds the foundation on the development of enhanced therapeutic strategies for many diseases, including cancer (Csermely *et al.*, 2016). So far, many molecular therapeutic approaches in cancer treatment have been based on the actionable mutations in kinase domains, which are the critical components in signaling pathways (Cheng *et al.*, 2014).

Extensive signaling studies have reconstructed a great number of carefully curated canonical signaling pathways, including the Jak-STAT, NF- κ B, Wnt, Notch, Ras/ERK, and G protein-coupled receptor pathways (Housden and Perrimon, 2014). These pathways form a complex network called signal transduction network (STN) (Kolch *et al.*, 2015) that allows cells to integrate multiple environmental signals, and respond with output signals specifically tailored to the environmental change or condition. In these STNs or subnetworks, nodes are primarily the molecules such as signaling proteins and microRNAs, while edges (links between STN nodes) are activating or inhibitory physical connections of participating signaling proteins, microRNAs and other regulators. The regulation involves in binding at the critical sites of the molecules, enzymatic reaction (e.g., phosphorylation and dephosphorylation), and allosteric regulation, among others (Csermely *et al.*, 2016).

The Raf–MEK–ERK MAPK Signaling Pathway in Cancer

There are many signaling pathways in our knowledgebase. For example, one of the popularly used pathway databases, Kyoto Encyclopedia of Genes and Genomes (KEGG) database, currently curates a total of 320 human pathways (Kanehisa *et al.*, 2016). Illustration of each pathway and how it works is beyond the scope of this article. Here, we take signaling pathway in cancer as one example. Tumorigenesis has been perceived as dysfunction of STNs that regulate molecular communications and cellular processes (Kolch *et al.*, 2015). During cancer initiation and development, the STN undergoes systematic changes in terms of expression level of nodes, as well as in the sign (inhibition or activation) and weight (strength) of their edges. Dysregulation of cellular signal transduction pathways underlies most well-defined features in cancer cells (Sever and Brugge, 2015). We performed literature survey using keywords “signal transduction”, “network”, and “cancer”. As shown in Fig. 1, it clearly shows the research in signaling pathways in cancer has been growing rapidly and consistently. We expect the number of cancer STN studies to increase substantially in the near future, considering that more –omics data and better pathway and network tools will be released in the near

Fig. 1 Number of publications (y -axis) from PubMed title/abstract search using keywords “signal transduction” AND “network” AND “cancer”. This simple search is not to have an exhaustive list but shows a strong trend of the growing studies in cancer by using signaling transduction network approaches.

future. To cover all of the signaling molecules involved and their myriad contributions to cancer would be too much in this article. We therefore focus on mitogen-activated protein kinase (MAPK or MAP kinase) signaling pathway, which attracts most attention and research interest due to its central role in regulating cell proliferation and survival and significant impact in various types of cancer (Roberts and Der, 2007; Cheng *et al.*, 2013).

In cancer, especially in melanoma (Cheng *et al.*, 2013), MAPK signaling cascades are critical and constitutively activated by a variety of mechanisms. These activation mechanisms, as well as the key genetic alterations detected in the pathway, have enabled the investigators to successfully develop kinase inhibitors and applied to the treatment of cancer, namely kinase or pathway based, molecularly targeted therapies. MAPK signaling pathway is one of key cellular mechanisms involving in cancer through promoting cell proliferation, survival, invasion, and tumor angiogenesis. This pathway consists of four widely studied MAP kinases, and these cascades sequentially transfer proliferative signals from the cell surface receptors into the nucleus via a series of protein phosphorylation events. Each MAPK cascade is comprised of three protein kinases that act as a signaling relay: MAP kinase kinase kinase (MAPKKK, MAP3K, or MEKK), MAP kinase kinase (MAPKK, MAP2K, or MEK), and MAPK. The four alternative terminal MAP kinases are the extracellular signal-regulated kinase 1 and 2 (ERK1/2), the c-Jun amino-terminal kinases (JNK12/3), p38 kinases, and ERK5. Among these four cascades, RAS-RAF-MEK-ERK1/2 pathway (Fig. 2) has attracted most research interest due to its central involvement in the regulation of cell proliferation and cell survival (Roberts and Der, 2007). In response to binding of various activators such as growth factors and hormones, receptor tyrosine kinases (RTKs; e.g., KIT) form a dimer, which causes the activation of Ras to GTP-bound state, and facilitates the recruitment of Raf (e.g., Braf) from the cytosol to cell membrane where it becomes an activated form. The adaptor protein growth factor receptor-bound protein 2 (Grb2), which comprises of Src homology 2 domain, promotes the binding of guanine nucleotide exchange factor son of sevenless (SOS), thereby leading to the formation of active Ras-GTP. Once being activated, Raf kinases phosphorylate and activate Mek proteins (Mek1 and Mek2), which subsequently lead to the phosphorylation and activation of Erk (Erk1 and Erk2). Finally, phosphorylated Erk1/2 proteins enter nucleus and regulate the activities of a large number of substrates – an estimate of over 160 proteins including ELK-1, Fos, Myc, and others – to control multiple cellular processes (Roberts and Der, 2007). The cascade of kinase reaction from RAF to MEK to ERK is a classic example of a signaling pathway. This pathway also represents an excellent example to illustrate feedback regulation (see below) and signal amplification.

Structural Motifs in STN

In a highly clustered STN, essential modules can be detected by identifying recurring patterns of highly interlinked groups of nodes (Liu *et al.*, 2008). A number of structural motifs exist in STNs, such as feed forward loops (FFLs) (Mangan and Alon, 2003) and feedback loops (FBLs) (Brandman and Meyer, 2008). These motifs enable a STN to respond selectively to a particular stimulus at the dynamic signal level, and therefore, result in precision action as the response.

The FFL (Mangan and Alon, 2003) is composed of three signaling molecules (e.g., transcription factors or microRNAs): a regulator (X) that regulates a molecule Y and targets a molecule Z, and Z is jointly regulated by X and Y. Because each of the three regulatory interactions in the FFL can be either positive (activation) or negative (repression), there are eight possible structural types of FFL (Fig. 3). Four of these FFLs are termed “coherent”, where the sign of the direct signaling path (from X to Z) is the same

Fig. 2 Schematic diagram of the MAPK signaling pathway and selected inhibitors.

as the overall sign of the indirect signaling path (from X through Y to Z). The remaining four FFL configurations are termed “incoherent” where the signs of the direct and indirect signaling paths are opposite. In complex disease research field, the FFL approach was first applied to schizophrenia in 2010, where 32 FFLs among the compiled schizophrenia-related transcription factors (TFs), miRNAs and genes were identified (Guo *et al.*, 2010). This approach has been frequently applied to cancer and other disease or phenotype since then, and a database for TF-miRNA-gene modules has been developed.

The FBL (Brandman and Meyer, 2008) is another common network motif that connect output signals back to their inputs. In this case, a downstream signaling molecule of a pathway activates (positive feedback) or represses (negative feedback) an upstream signaling molecule (Fig. 3). Positive FBLs can be utilized to control the response of a signaling pathway to different stimulation durations by locking the system into an on or off state following a transient signal. On the contrary, negative FBLs can cause a change in the dynamics of signaling because in that scenario, an activation of the signaling pathway can subsequently lead to a repression of the same pathway. And this may have several different effects depending on the kinetics of the FBL. FBL as a motif unit has been widely used in biomedical and biological research, such as the kinase cascade introduced in the subsection ‘The Raf–MEK–ERK MAPK signaling pathway in cancer’.

STN Databases and Enrichment Analysis Tools

There have been numerous studies of STNs or the subcomponents of a STN. The rich information has been available from literatures, databases and other resources. Accordingly, knowledgebase on STNs has become one of the important efforts to summarize the previous findings. Such knowledgebase can provide us with a systematic view of the biological processes and assist us for future studies of disease mechanisms (Liu *et al.*, 2008). To meet various needs, researchers have established many databases through careful curation and storage of such data, as well as allowing users to access and visualize the biological pathways and molecular interactions (Table 1). Among these databases, KEGG database (Kanehisa *et al.*, 2016) is one of the popular, manually curated pathway resources. It includes the knowledge in the molecular interaction, reaction and relation networks, and pharmacological information. KEGG consists of seven types of network context: metabolism, genetic information processing, environmental information processing, cellular processes, organismal systems, human diseases, and drug development. The KEGG pathway information is machine-readable via KEGG Markup Language. KEGG includes many canonical signaling transduction pathways. It was initially publicly available but later the access requires fee-based subscription. Reactome (Fabregat *et al.*, 2014) is another popular, well curated, and peer reviewed pathway database. The current version (V62) comprises 11,302 reactions (e.g.,

Fig. 3 Motifs of feed forward loop (FFL) and feedback loop (FBL) in signal transduction network. (A) The eight types of FFLs can be classified into four coherent and four incoherent FFLs. In coherent FFLs, the sign of the direct path from signaling molecule X to output Z is the same as the overall sign of the indirect path through signaling molecule Y. Incoherent FFLs have inconsistent or opposite signs for the two paths. (B) The two types of FBLs: a downstream molecule activates (positive FBL) or represses (negative FBL) an upstream molecule.

phosphorylation, acetylation, etc.) organized into 2176 human pathways, involved in 10,878 proteins and 1768 small molecules. These data were extracted from 27,526 publications. For machine readability, Reactome adopted the Systems Biology Markup Language (SBML) format for systematic access and analysis. In addition to those self-curated pathway databases, other databases assemble different sources of pathways. For example, the Pathway Commons database (Cerami *et al.*, 2011) contains extensive collection of pathway and interaction data from partner databases such as KEGG, Reactome, and MSigDB (the Molecular Signatures Database) (Subramanian *et al.*, 2005) and is represented in the Biological Pathway Exchange (BioPAX) standard. WikiPathways (Kutmon *et al.*, 2016) is another integrated database of biological pathways maintained by and for the scientific community. The advantage of WikiPathways lies in the scalable, community-based curation and unrestricted pathway model through accepting any pathway that researchers find useful in their work. Table 1 provides a list of pathway databases, including the description and access URLs. Each of these pathway databases include signaling transduction pathways.

Table 1 Summary of databases and tools for signaling transduction networks

Name	URLs	Description
KEGG	www.genome.jp/kegg/pathway.html	A collection of manually pathway maps representing our knowledge on the molecular interaction, reaction and relation networks
Reactome	www.reactome.org	A free, open-source, curated and peer reviewed pathway database
Gene Ontology	www.geneontology.org	A computational representation of gene products in terms of their associated biological processes, cellular components and molecular functions
Pathway Commons	www.pathwaycommons.org	An integrated resource from public pathway and interactions databases
NCI PID	https://pid.nci.nih.gov	Biomolecular interactions and cellular processes assembled into authoritative human signaling pathways
BioCarta	https://cgap.nci.nih.gov/Pathways/BioCarta_Pathways	Online maps of metabolic and signaling pathways
WikiPathways	www.wikipathways.org	A database of biological pathways maintained by and for the scientific community
UCSD Signaling Gateway	www.signalinggateway.org	A database providing essential information on the proteins involved in cell signaling
MSigDB	https://software.broadinstitute.org/gsea/msigdb	A collection of annotated gene sets for gene set enrichment analysis
NetPath	www.netpath.org	A manually curated resource of signal transduction pathways in humans
Signalink	www.signalink.org	A signaling pathway resource with multi-layered regulatory networks
Pascal	www2.unil.ch/cbg/index.php?title=Pascal	A tool for gene scoring and pathway analysis from GWAS results
DAVID	https://david.ncifcrf.gov	A comprehensive set of functional annotation tools to understand biological meaning behind large list of genes
webGestalt	www.webgestalt.org	A suite of tools for functional enrichment analysis in various biological contexts
Ingenuity	www.qiagenbioinformatics.com/products/ingenuity-pathway-analysis	A comprehensive analysis and search tool of global molecular network based on manual curation
ToppGene	https://toppgene.cchmc.org	A portal for gene list enrichment analysis and candidate gene prioritization based on functional annotations and protein interactions network

Based on the prior knowledge (pathway databases), many tools have been developed to interpret gene lists derived from the high-throughput experiments (Wadi *et al.*, 2016). These pathway analysis tools use various strategies to aggregate genes across sets of the related genes (Table 1). The most common approach used for gene set enrichment of pathway function is based on binary enrichment tests, which rely on a threshold parameter to determine which genes are significantly associated with the disease or trait. One disadvantage of such an approach is that potential contributions of the weakly associated genes that just missed the threshold would be lost and there is no clear rule on the threshold setting. To address this problem, Lamparter *et al.* (2016) presented a powerful tool called Pascal (Pathway scoring algorithm) for computing pathway scores. Pascal integrates individual gene scores without the need for a tunable threshold parameter to dichotomize gene scores for binary membership enrichment analysis. As a result, it shows better discovery of confirmed pathways compared with other popular methods. However, challenges and limitations exist in all the pathway enrichment methods currently available. These challenges include the multiple test correction, redundancy of the genes shared by different pathways, appropriate statistical tests, incomplete pathway data being available to test, and gene length bias on measuring the signals from the genomic data, among others (Jia *et al.*, 2011; Wang *et al.*, 2010).

Computational Modeling of STNs and Its Applications

In this section, we present several examples of the computational modeling of STNs.

Genetic Mutations Impact STNs

Somatic mutations may cause abnormal cell growth, resulting in tumorigenesis. These mutations confer a selective advantage to the cancer cells, which together with changes in the microenvironment, promote cancer growth and progression. Analyses of massive amounts of cancer genomics data generated from several large-scale cancer genome sequencing projects such as The

Cancer Genome Atlas (TCGA) and the International Cancer Genome Consortium (ICGC) have discovered more than 68 million simple somatic mutations and many other types of somatic mutations (as of December 11, 2017). However, most of these mutations are passenger mutations. Typically, only two to eight in a cancer cell are driver mutations that cause progression of the cancer (Vogelstein *et al.*, 2013). These may be single-nucleotide variants, small insertions or deletions, copy number variations, or structure variants.

Based on these mutation data, we can connect the genetic mutations in cancer cells within STNs that control processes associated with tumorigenesis and place them in the context of distortions of wider STNs that fuel cancer progression. Genetic mutations can cause abnormal expression of proteins involved in a STN (e.g., gene amplification) or change the individual contributions of a specific STN by producing mutant proteins whose activities are dysregulated (e.g., point mutations, truncations, and fusions). Alternatively, deletions in genes may inactivate negative regulators, which may cause the absence of the specific nodes within a STN. Moreover, multiple mutations can occur within a cell simultaneously and among cells of a specific tumor type. Recently, Zhao *et al.* (2017) proposed a computational oncoproteomics approach, namely kinome-wide network module for cancer pharmacogenomics (KNMPx), for identifying actionable mutations that rewired STNs by incorporating the somatic missense mutations into the protein phosphorylation sites. Specifically, 746,631 missense mutations in 4997 tumor samples across 16 major cancer types/subtypes from TCGA were integrated into over 170,000 carefully curated non-redundant phosphorylation sites covering 18,610 proteins. Forty-seven mutated proteins (e.g., ERBB2, TP53, and CTNNB1) had enriched missense mutations at their phosphorylation sites in pan-cancer analysis. In addition, tissue-specific kinase-substrate interaction modules altered by somatic mutations that were identified in cancer genomes were significantly associated with patient survival. Interestingly, the authors found that cell lines could highly reproduce oncogenic phosphorylation site mutations identified in primary tumors, supporting the confidence in their associations with sensitivity/resistance of inhibitors targeting EGF, MAPK, PI3K, mTOR, and Wnt signaling pathways. According to the results, the KNMPx approach is powerful for identifying oncogenic alterations in signaling molecules via rewiring phosphorylation-related STNs and for predicting drug sensitivity or resistance in the era of precision oncology.

Pan-Cancer Analysis of Dysregulated Transcription Factor – microRNA FFLs in STNs

Transcription factor and microRNA (miRNA) can mutually regulate each other and jointly regulate their shared target genes. This is an ideal example for FFLs in cellular system. Since 2010, TF-miRNA FFLs have been widely used to identify the cancer-associated genes or miRNAs in many tumor types. As one example, Jiang *et al.* examined dysregulated FFLs in pan-cancer (13 cancer types) (Jiang *et al.*, 2016). They identified 26 pan-cancer FFLs, each of which was found to be dysregulated in at least five tumor types using TCGA data. They found these pan-cancer FFLs could communicate with each other and form functionally consistent subnetworks, such as epithelial to mesenchymal transition-related subnetwork. Many proteins and miRNAs in each subnetwork belong to the same protein family and miRNA family, respectively. Importantly, cancer-associated genes and drug targets were enriched in these pan-cancer FFLs, in which the genes and miRNAs also tended to be hubs and bottlenecks. In addition, they identified potential anticancer indications for existing drugs with novel mechanism of action. Collectively, their study demonstrated the potential of pan-cancer FFLs as critical regulatory units that are useful for elucidating pathogenesis of cancer and developing anticancer drugs.

Decipher STNs for Drug Effect in Complex Disease

A drug exerts its effects typically through a STN cascade, which is non-linear and involves intertwined networks of multiple signaling pathways. Construction of such a STN may help the investigators to identify novel drug targets and further understand drug action. Sun *et al.* developed a novel computational framework, the Drug-specific Signaling Pathway Network (DSPNet), to tackle this issue (Sun *et al.*, 2015). The DSPNet amalgamates the prior drug knowledge and drug-induced gene expression via random walk algorithms. Using the drug metformin as an example, they illustrated this framework and obtained one metformin-specific SPNetwork containing 477 nodes and 1366 edges. The further examination of this subnetwork using one type 2 diabetes (T2D) genome-wide association study (GWAS) dataset, three cancer GWAS datasets, and one GWAS dataset of cancer patients with T2D on metformin indicated that the metformin network was significantly enriched with disease genes for both T2D and cancer, and that the network also included genes that may be associated with metformin-associated cancer survival. The authors also generated a subnetwork to highlight the molecules' crosstalk between T2D and cancer. The follow-up network analyses and literature mining revealed that some valuable insights into the mode of metformin action, which will facilitate our understanding of the molecular mechanisms underlying drug treatments, disease pathogenesis, and identification of novel drug targets and repurposed drugs. As many drugs may target signaling molecules, or through metabolism that links to signaling pathways, novel computational approaches for deciphering STNs will be much needed.

Applications of STNs in Other Fields

Besides cancer, STNs have been frequently used to study the molecular regulation in specific cellular conditions, cell types, epigenetic regulation, or in other complex disease or phenotype. For example, Bernabò *et al.* have applied STN approach to

investigate the cell signal transduction, which is a complex phenomenon and has a central role in cell surviving and adaptation, in non-medical systems. The authors presented two applications of STNs for cell signaling. One is to study the architecture of signaling systems for acquisition of a complex cellular function (i.e., process of activation of spermatozoa) and the other is to find the organization of specific signaling systems that are active in specific cells and/or tissues (i.e., the endocannabinoid system) (Bernabò *et al.*, 2014). In both the applications, the authors found that the STNs follow a scale free and small world topology. Such network characteristics will allow the investigators to identify molecules (e.g., hubs) or modules that play key role in signaling system. STNs approaches have also been applied to study human pluripotent stem cells. As an example, Fgf/MAPK, TGF β /SMAD2,3 and insulin/PI3K signaling pathways are found to be required for maintenance of the stem cell state (Dalton, 2013). Moreover, DNA methylation data has been integrated with other genomic data into STNs for exploring epigenetic regulation patterns for complex disease like bone mineral density (BMD) (Zhang *et al.*, 2015). In synthetic biology field, the progress of STN approaches in synthetic signal transduction implementation has been systematically reviewed in diverse biological contexts including bacteria, yeast, vertebrate, and plant cells (Hansen and Benenson, 2016), and various systems STN concepts have been implemented into metabolic engineering and synthetic biology (He *et al.*, 2016).

Closing Remarks

Complex disease like cancer is highly heterogeneous – it involves dynamic regulation and interactions of STNs at the cellular level. It is often tissue-specific and development stage specific. Identification of STN changes that are critical for cell function, development, or drug binding will substantially improve our knowledge and have potential for healthcare. As we have entered the big data era, we expect more novel, systematic studies will be conducted, leading to not only knowledge discovery in signaling pathways and networks, but also more disease mutations and drug-targetable sites. Advanced statistical and computational methods and tools will be further needed to meet such a strong demand in future. For example, novel tools that can effectively integrate the genomic and genetic data in a spatiotemporal fashion into the STNs will power the investigators to measure the genetic or biological changes in high resolution and more reflective on the cellular condition.

Introduction

Since the 21st century has begun, the so-called post-genome era, the biggest open questions are how the phenotype is generated from the genotype, and how evolution is achieved from the phenotype. Towards this ultimate goal, systems biology has emerged as a conceptual approach to understand life as an evolvable and robust system (Kitano, 2002). Mathematical modeling and simulation of the biological systems have played the central role in the context of systems-level understanding and predictability of living organisms (Fig. 1).

As with modeling of other systems, the abstraction of the cell properties is the first key step in cell modeling. This step requires the definition of boundaries in the focused cellular system.

The cell contains highly integrated subsystems in itself, although it is often called a building unit for the structure and function of living organisms. The complexity lays in space and time. Moreover, although the cell has independent replicability, its activity is dependent not only internal state but also extrinsic perturbations, that is, its surroundings, which are orchestrated towards robust biological functions. It is thus difficult to define physical and functional boundaries in the cellular system, as is clear from the fact that the cellular behavior observed in vitro is hardly reproduced in vitro. Under these circumstances, cell simulation often requires drastic abstraction of the system to keep the balance of desired trade-offs with predictability.

The demands for cell simulations are also largely regulated by how the technology in molecular biology has evolved. The electronic kinetics emerged in the 1950s and drove the first mathematical modeling of cellular phenotypes reported by Hodgkin–Huxley (Hodgkin and Huxley, 1952), focusing on the dynamics of heart activity by calculating the ensemble of voltage-dependent channels using nonlinear ordinary differential equations, which is still a basis for studying the behavior of ion channels. The protein purification led to massive studies on enzymes in the 1970s that initiated metabolic simulations based on enzyme kinetics (Garfinkel *et al.*, 1970; Heinrich *et al.*, 1978; Tyson and Othmer, 1978). From the late 1990s to the present, with genomics as a start, comprehensive measurements of each biological layer have emerged, including metabolomics, proteomics, and epigenomics, and have changed our view of biological systems towards data-driven science (Hey *et al.*, 2009). In recent years, it has become possible to observe cell behaviors at the single cell resolution (Kalisky *et al.*, 2011; Xia *et al.*, 2013). This has made us aware of the significance of cell–cell heterogeneity at the population level (Iwamoto *et al.*, 2016), inter- and intracellular spatio-temporal dynamics considering diffusion and reaction kinetics (Takahashi *et al.*, 2005), and inherent biological noise (Mettetal *et al.*, 2006).

Simulation models where essential components in the system are appropriately defined and assembled can predict the system's response towards given perturbations. The hypothesis derived from such simulation then becomes valuable for experimental validations. The simulation–experiment cycle through mathematical models can minimize costly or impossible experiments such as sensitivity analysis, impact estimation of unknown factors, assessment of systems threshold, or finding necessary and sufficient minimum components for the focused event.

Approaches in Cell Simulation

Due to the complexity in both cellular systems and the demands for cell simulation, a variety of approaches and methods have been considerable, depending on the feature of the focused system including cell type and phenomena, the accessibility to the system, and the availability of the data (Fig. 2).

Dynamic Modeling and Static Modeling

The first decision branch on cell modeling is the definition of time in the simulation. Dynamic models typified by ordinary differential equations (ODEs) and partial differential equations (PDEs) determine the time development of the cellular system based on the precedent states and response to the environmental changes.

On the other hand, static cell models represent the analysis of the static diagrams of model components, including their attributes and relationships between components. For example, for metabolic systems, topological pathway analysis such as elementary modes (Schuster *et al.*, 2000) and extreme pathways (Schilling *et al.*, 2000) predict essential chain of processes by using stoichiometric relationships and mass conservation law. Metabolic flux analysis is also a stoichiometry-based static model to predict gross error and flux distribution of the metabolic system by introducing flux measurements into the pathway topology (Zupke and Stephanopoulos, 1994; Schmidt *et al.*, 1997). Metabolic control analysis is the static modeling to predict rate or pool controlling steps from the pathway diagram (Fell, 1992). In a broader sense, the static modeling can be expanded to include the generation of comprehensive networks of physical and functional interactions between cellular components by certain network

Fig. 1 A roadmap in predictive biology based on cell modeling and simulation. Once we define the cell system, the system is modeled through mathematical formulation based on data. The model is then used to predict the focused cellular phenomena to be validated. The prediction generates, strengthens, or refines the hypothesis on cell system, which drives another cycle of the road map.

Fig. 2 Simulation approaches of cell systems. Cell modeling is starting from the selection of the suitable mathematical framework from a variety of simulation approaches displayed along several axes. Horizontal axis and vertical axis sort out simulation techniques by mechanistic or logic, dynamic or static, respectively. In addition, dynamic approaches are also split into two groups depending on stochasticity (deterministic or stochastic). Abbreviation used: ODE (ordinary differential equation), PDE (partial differential equation), FBA (flux balance analysis), SSA (stochastic simulation algorithm), EPA (extreme pathway analysis), MCA (metabolic control analysis), EFM (elementary flux mode).

inference approaches (Marbach *et al.*, 2012), or manual curation of the molecular pathway maps (Oda *et al.*, 2005; Oda and Kitano, 2006; Kaizu *et al.*, 2010; Matsuoka *et al.*, 2013).

Deterministic Simulation and Stochastic Simulation

One of the major aspects segregating approaches of cell simulation is the consideration of the stochasticity in the processes. Deterministic behavior can be defined as a consecutive chain of precedent events where no randomness is affecting the next states. In this sense, deterministic cellular models reproduce the same predictions for a given initial condition. This is applicable in case of well-stirred systems, in other words, the systems where cell behavior can be assumed as the behavior of the cell population where the cell belongs.

However, in case the target cell system is assuming small volumes or small numbers of molecules, this definition of deterministic behavior is not applicable (Rao *et al.*, 2002), and stochasticity of the process should be introduced, such as the Gillespie algorithm (Gillespie, 1977). For example, each transcription process is governed by a specific transcription factor whose number is as low as several dozen (Elowitz *et al.*, 2002), and the deterministic modeling can no longer reflect the behavior of cell systems. Moreover, recent emergence of single cell tracking techniques shed light on the stochastic fluctuations of molecules, which exert large impact on significant processes (Gillespie, 2007).

Mechanism-Based Modeling and Logic-Based Modeling

Modeling of the cell system considering biochemical properties for each process, for example, biochemical rules, requires a large amount of mechanistic and quantitative information. This shortage of data on modeling has never been solved despite the rapid spread of high-throughput technologies, as the mechanism-based modeling requires data restricted to influential range of the focused variables while the high-throughput data typically provide more macroscopic view.

Logic-based models are the alternative approaches to overcome the issue around data availability where relationships between variables are described without molecular details, such as Boolean models, fuzzy logic models, and Petri-net models (Kauffman, 1969; Reddy *et al.*, 1996; Hofestadt and Thelen, 1998; Aldridge *et al.*, 2009). Logic-based models assume that one variable respond to the others in a gate (switch-like) fashion (Watterson *et al.*, 2008; Morris *et al.*, 2010; Wynn *et al.*, 2012; Le Novère, 2015). This mathematical simplification is analogous to a steep Hill function with high cooperativity while dose-response features can't be represented. In contrast, it may be feasible to some extent, for example, to apply logic-based modeling to predict the gene expression patterns, with the generally applicable fact that gene expression is a bimodality distributed at the single cell level (Shalek *et al.* 2013).

Simulation Models in Biological Layers

Simulation models are focused on specific phenotype and thus generally focused on specific biological layers. Due to the characteristics of each layer, frequently applied approaches are varied.

Metabolism

The nature of metabolism is the well-regulated mass transfer reaction chains of small molecules called metabolites, whose number is enough large in most cases to assume well-stirred systems. Due to these characteristics of metabolic pathways, dynamic, deterministic and mechanistic approach has been dominantly applied empowered by the massive studies of enzyme kinetics. The case example of modeling of red blood cell metabolism and its application is discussed in the following section.

On the other hand, apart from the dynamic kinetic models, cellular metabolic systems have long played a central role in the tight connectivity between mathematics and wet-lab biological experiments, specifically in the area of systems control theory in metabolic engineering. Indeed, the distinguished scientists in metabolic engineering and their studies took the stage when systems biology emerged and formed as a field (see the subsection "Dynamic Modeling and Static Modeling" in the section "Approaches in Cell Simulation"). Under the mass conservation law and the steady-state assumption, which is relatively fair in metabolism given the robust metabolic homeostasis, it is possible to calculate the flux distribution of the given metabolic system, called flux balance analysis (FBA; Orth *et al.*, 2010). Further assumptions that the cell metabolism is optimized or can be engineered towards the objective cellular functions introduce optimization techniques into FBA to examine the ideal space of metabolic states (i.e., flux distribution patterns), which is called constraint-based modeling (O'Brien *et al.*, 2015; Oberhardt *et al.*, 2009). We now have information from genomes in most model organisms and their annotations with high quality, and thus have a comprehensive topology comprising metabolic reactions at whole-genome scale (Bao and Eddy, 2003). In addition to the bottom-up reconstruction of the model, top-down integration of high-throughput measurements as a further constraint has led the increasingly relevant predictions on cell metabolism (Bordbar *et al.*, 2014). For example, the constraint-models of a genome-scale metabolic pathway have been applied to engineer a strain of *Escherichia coli* producing a valuable chemical, such as L-threonine and 1,4-Butanediol (Lee *et al.*, 2007; Yim *et al.*, 2011), and those of human metabolism have predicted tissue-specific significance of disease gene activity (Shlomi *et al.*, 2008; Jerby *et al.*, 2010).

Signaling

In contrast to metabolic pathways where small molecules and their mass transfer processes are the major variables and processes, the central components of signaling pathways are proteins and the sets of chemical chain reactions based on their states, which is called a signaling cascade. In addition, the key signaling cascades often contain physical information transfer such as nuclear translocations, as the signal propagation should occur in a local and restricted environment. This nature of cellular signaling has called modelers' attention toward spatiotemporal approaches, as described in the section "Spatial Simulation Techniques."

The cellular response to biological signals is significantly varied in contrast to the limited number of known signaling molecules and their cascades. Nevertheless the biological phenomena as a final outcome of the signaling cascade are decoded and often digitized, such as cell fate decision. Due to this discreteness and the dynamic variations of the systems output, the consideration of stochasticity of each process is important in modeling of signaling systems. Remarkably, the models have predicted the significance of stochasticity in small subcellular volume for the propagation of information through certain signaling cascade (Bhalla, 2004a,b, Fujii *et al.*, 2017).

Logic-based modeling approaches have also been applied to simulate signaling cascades (Morris *et al.*, 2010) while the detailed mechanistic and kinetic models of signaling systems have given us significant insights on both fundamental topology and hidden dynamics of the signaling cascade (Kholodenko, 2006). For example, using the mitogen-activated protein kinase signaling model, it has been revealed that the frequently observed signaling cascade arrangement has unexpected consequences for the dynamics that can give an ultrasensitive response to input signal (Huang and Ferrell, 1996). It has been also revealed by the kinetic model that transiently high and sustained concentration of the upstream input signal make different outputs of extracellular-signal-regulated kinase signaling cascade (Sasagawa *et al.*, 2005). This indicated that cell systems encode the distinct dynamics of signals to specific proteins using the signaling cascade to keep the variations of cellular response with minimum set of molecules.

Gene Regulatory Networks

A gene regulatory network (GRN) is a collection of regulatory relationships between transcription factors (TFs) and TF-binding sites of specific mRNA to govern certain expression levels of mRNA and their resulted proteins. Up to 10% of the ORF-coding genomes are coding TFs (Levine and Tjian, 2003) each of which are highly interconnected in the GRN. The GRN itself is often recognized as a static model and frequently described as a large “graph” consisting of hundreds of TFs where nodes represent TFs and edges between nodes represent regulatory relationships between them. The edges in the GRN graph are assessed experimentally by the detection of protein–DNA interactions through chromatin immunoprecipitation techniques (Lee *et al.*, 2002; Ren *et al.*, 2000; Robertson *et al.*, 2007; Johnson *et al.*, 2007; Mikkelsen *et al.*, 2007) or protein–protein interactions (Fields and Song, 1989; Chien *et al.*, 1991). The computational approaches have also been massively developed (Bansal *et al.*, 2007; Ideker and Krogan, 2012; Marbach *et al.*, 2012) to infer GRNs.

Apart from static modeling, dynamic approaches to model GRNs have considerable difficulties including the time delay between transcription and translation, and the shortage of information on the essential topology to represent the focused phenotype and the kinetics. In this context, logic-based models have frequently been applied to simulate and understand the transient states of GRNs (Chai *et al.*, 2014). A recent attempt identified a minimal set of nodes (genes) and their interactions sufficient to explain the experimentally observed cell behavior, by automated reasoning using Boolean models with possible interactions in the GRN in mouse embryonic stem cells (Dunn *et al.*, 2014).

Nevertheless, cell fate transitions occur when cells switch from one GRN to another. Boundaries between these cell states are influenced both by intrinsic fluctuation expression (Eldar and Elowitz, 2010; Singer *et al.*, 2014) and by extrinsic variations in the cellular microenvironment. Moreover, cell–cell heterogeneity of GRN states is commonly observed that can yield stochastic single cell state transitions coalescing into a stable cell population (Glauche *et al.*, 2010; Herberg *et al.*, 2014). To tackle these fundamental properties of GRNs while keeping predictive power, the novel simulation framework has been developed based on asynchronous Boolean simulation followed by graph-theory analysis of the GRN state-transitions (Yachie-Kinoshita *et al.*, 2017). The simulation quantitatively depicts the dynamic changes in cellular GRN states as a function of signaling inputs and their consequential feedback loops within the GRN. The outputs from the simulation provide predictions of the probability of transitions between distinct single cell states, population-average expression frequencies, and the emergence of stable subpopulations in response to different input conditions. The simulation framework was then applied to a relatively large GRN (around 30 nodes in the graph) in mouse embryonic stem cells and five major signaling pathways around pluripotency. As a result, the model predicted a novel combination of signaling inputs that drives mESCs to a specific cell fate.

Application of Predictive Kinetic Model

Red blood cell metabolism and its enzymology have been well studied over the last four decades due to its availability as human cell samples and relative simplicity where the mature cells lack the dynamism from gene expression and the individual cells are physically and functionally compartmentalized via the cell membrane. Although the essential biochemical pathways in red blood cells to maintain the cell state are established earlier and the kinetic information corresponding to each enzymatic reaction in these pathways is available, the quantitative and physiological role of the metabolism is still an open question, because the nature of the cellular function is the complex dynamics of all metabolites.

The ODE-based model of the comprehensive red blood cell metabolism representing detailed enzyme kinetics was then constructed on the E-Cell simulation platform (Takahashi *et al.*, 2004). The model comprises nearly 100 reactions and around 50 metabolites each of which belongs to glycolysis, pentose phosphate pathway, purine salvage pathway, membrane transports, ion leak processes, ATP (adenosine triphosphate)-dependent Na^+/K^+ pump process, or binding reactions between metabolites (Kinoshita *et al.*, 2007a,b).

The initial role of this model was to predict acute hypoxic response of red blood cell metabolism to understand the cellular states in microcirculation. To this end, the hemoglobin allostery in binding and releasing oxygen was modeled in ODE formalism, as well as the binding reactions between key energy metabolites and distinct forms of hemoglobin with and without oxygen.

In the simulation of hypoxia, the oxygen pressure was set from 100 mmHg (arterial level) to 30 mmHg (venous level), then the predicted dynamics in metabolite concentrations were compared with the experimental data from metabolome analysis. The predicted hypoxia response from the model was not in agreement with the experimental data from metabolome analysis; rather no remarkable dynamics was predicted upon state transition of hemoglobins, in spite of that the model successfully reproduce the metabolic states upon other environmental or genetic changes of enzymes.

Given the discrepancy between the prediction and the validation, the model was then refined and expanded to include the other biochemical events by literature curation focusing on connectivity between hemoglobins and metabolism. It is known that both hemoglobin forms with and without oxygen bind to a membrane anion transporter protein called band 3 in distinct association constants. Separately, it is also proved that three enzymes catalyzing intermediate steps of glycolysis also bind to band 3 membrane protein. The model refinement step was carried out by the curation and implementation of these binding processes with distinct kinetic parameters, that is, binding constants.

The refined model considering band 3 membrane protein successfully predicted the measured dynamics. These results from the simulation–experiment cycle indicated the significance of this protein for the metabolic alteration during hypoxia as well as the hypothesized nature of hypoxic response of metabolism where the hemoglobin state transition is the dominant factor of acute changes of red blood cell metabolism upon hypoxia. Moreover, from the analysis of the model, it was predicted that this hypoxic response is necessary to maintain metabolic resources (ATP and 2,3-bisphosphoglycerate (2,3-BPG)) in red blood cells during hypoxia. These hypotheses were confirmed by the biochemical experiment using carbon monoxide-treated hemoglobins, which can mimic the oxygen-containing form of hemoglobin without oxygen molecule.

This precise and predictive model of red blood cell metabolism has further been applied to predict the residual content of metabolic resources in practical long-term storage (Nishino *et al.*, 2009; Nishino *et al.*, 2013). The kinetic parameters of the model are to be altered by temperature, time, and the storage solution. In the modeling studies, these unknown parameters were estimated by real number genetic algorithm to fit with experimental measurements of time course changes in key metabolite concentrations in preserved red blood cells. As a result of the parameter calibration, the model successfully reproduced the dynamics of intermediate metabolites measured in metabolome analysis. The simulation analysis of the model predicted the fates and roles of additive metabolites in the solution for red blood cell storage, which showed somewhat of a trade-off and interlocking relationships between the benefits and possible side effects.

The predictive models and the validation experiments in this way can help us to generate testable hypothesis through the model refinement cycles and give insights to design cellular behaviors (Fig. 1).

Spatial Simulation Techniques

The rapid progress in spatial simulation techniques together with the significant developments in advanced single-molecule measurement such as TIRF (total internal reflection fluorescence) microscopy, and FRET (fluorescence resonance energy transfer) (Liu *et al.*, 2015) enables various applications to study significant cellular phenomena, which are hardly assumed to be spatially uniform.

A conventional way of spatial representation of the cell system is compartmental modeling, where an intracellular space is partitioned into compartments, such as cytoplasm, nucleus, and membrane (Fig. 3(a)). Each compartment is assumed to be well-stirred and the molecules are distributed uniformly in it. In the compartmental modeling framework, the systems dynamics, that is, time-dependent changes of molecular concentrations are either deterministically formulated as ODEs or a chemical master equation for the kinetic reactions, or stochastically formulated as a stochastic simulation algorithm typed by the Gillespie method to be numerically calculated for the chemical system taking into account its intrinsic fluctuation.

On the other hand, the mesh model is widely applied to take account of spatial heterogeneity of molecular distribution in the cell (Fig. 3(b)). In the mesh models, intracellular space is divided into small mesh or subvolumes (0.1–1 μm , in general). Molecules diffuse between neighboring subvolumes, and react in each subvolume. In the deterministic formalization, the chemical reaction–diffusion system is represented as PDEs, and is solved by finite element method, a widely used and common approach in various scientific fields. Various implementations of stochastic algorithms have been proposed for the mesh model with Gillespie method-based stochasticity (see Table 1 for the mesoscopic scope). The mesh models with multiple molecules in each voxel are also known as a mesoscopic lattice model. For example, distinct spatial patterns of synaptic response have been studied by mesh modeling of dendrites and spines (Blackwell, 2013).

Furthermore, along with the improvement in spatio-temporal resolutions of measurements, single molecule-level biophysical approaches have emerged where chemical reactions and diffusion processes of individual molecules are represented rather than the number or concentration of each molecule. As contrasted with mesoscopic lattice method, this type of modeling approach where each molecule occupies a molecular-scale voxel (typically few nanometers) is called the microscopic lattice method (Fig. 3(c)). In the microscopic lattice models, each molecule diffuses across a lattice, and reacts with another molecule at the collision (Arjunan and Tomita, 2010; Arjunan and Takahashi, 2017). The successful models with this type of approach have shown good agreement with experimental observations even with single-particle tracking (SPT) microscopy (Watabe *et al.*, 2015; Lindén *et al.*, 2016).

Yet another modeling approach for spatio-temporal simulation is the particle method based on Brownian dynamics, which treats molecules explicitly as particles, enabling a nanoscale simulation in continuous space (Fig. 3(d)). The Brownian dynamics (BD) method

Fig. 3 Spatial representations and simulation approaches. (a) The compartmental model is based on the numbers or concentrations of molecules in well-stirred compartments. The spatial resolution is comparable to the size of cell, nucleus, and organelles (about 1–100 μm). (b) The mesh and mesoscopic lattice models discretize a space into small volumes or areas. Each subvolume can contain multiple molecules in it. Molecules diffuse between and react in subvolumes. The length scale is smaller than a cell but larger than a molecule (0.1–1 μm). (c) The microscopic lattice model consists of small voxels that have the same size with molecules (1–100 nm). A molecule occupies a voxel at the location, and other molecules cannot penetrate there. (d) In the particle model, a molecule is explicitly represented as a particle or a set of particles in continuous space.

generally takes significantly long time to simulate the models and is assumed not applicable to the practical simulations of cell behavior. However, recently developed algorithms with remarkable speed-up have pushed the field towards cellular scale simulation with particle model in several minutes (Schöneberg *et al.*, 2014). As one of the representative particle simulations, Green's function reaction dynamics (GFRD) has accomplished fast and exact simulations of the many-body problem by decomposing it into one- and two-body problems while applying the analytical solution in an event-driven manner (Van Zon and Ten Wolde, 2005; Opplestrup *et al.*, 2006). In the context of the particle simulations at the single-molecule level, various representations of molecules can be applied (Schöneberg *et al.*, 2014). The particle model describes the molecule as a point particle (Andrews, 2017; Plimpton and Slepoy, 2005; Kerr *et al.*, 2008), as a sphere (Takahashi *et al.*, 2010; Klann *et al.*, 2011), or as a collection of spheres resembling molecular structure (Schöneberg and Noé, 2013; Michalski and Loew, 2016; Vijaykumar *et al.*, 2017). For example, GFRD-based particle modeling of ligand-receptor reactions predicted sensing efficiency in bacterial chemotaxis against biological noise (Kaizu *et al.*, 2014).

Tools for Cell Modeling and Simulation

Here we provide an up-to-date list of software and tools for cellular modeling and simulation (Table 1). Due to increasing need for integration of multiple models and approaches, extensibility has become a key factor in tool selection. In this context, the license information for each software package or tool has also been provided in the comprehensive list.

Discussion

Given the emergence of high-throughput and high-resolution experimental techniques as well as the demand for predictive science in cell biology, "whole-cell simulation" is now set as an ultimate but intended goal of systems biology (Tomita *et al.*, 1999; Karr *et al.*, 2012). Whole-cell modeling is a set of challenges in various aspects including modeling approaches, software connectivity, and big data handling (Karr *et al.*, 2015; Goldberg *et al.*, 2018).

For example, as discussed in the section of “Simulation Models in Biological Layers,” each biological layer has distinct scales of time, space, and quantity, all of which are orchestrated into one cell system. The integration of distinct biological scales so far cannot be done with a single simulation algorithm. In this context, for example, the E-Cell System originally launched in 1996 (Tomita *et al.*, 1997; Tomita *et al.*, 1999) endeavors to model and simulate the distinct spatio-temporal scales at the same time by developing a mathematical framework to combine multi-algorithms and multi-timescales (Takahashi *et al.*, 2004; The E-Cell System version 4).

As in the up-to-date list in Table 1, we now have a variety of tools and software, each of which has different focus on applicable biological layers, simulation algorithms, and usabilities. Under these circumstances, the need for unified platform to support multi-tools has become more apparent. From the “soft power” point of view, a standard format of simulation model would increase exchangeability among simulation tools and reproducibility and reusability of the models are secured. The Systems Biology Markup Language (SBML) has been developed and now popularized in the scientific community (Hucka *et al.*, 2003; Hucka *et al.*, 2015; Waltemath *et al.*, 2016). The movement of packaging software for cell modeling and simulation has also come out such as BioNetGen (Blinov *et al.*, 2004) and PySB for Python-based programmatic model construction (Lopez *et al.*, 2013).

The scalability of the simulation models towards whole-cell simulation is largely dependent on (generally experimental) data availability and its accessibility. The complete computational workflow including data collection, data mining, network inference, modeling, simulation, model analysis, and model validation has to be executed to complete the systems biology roadmap and that should be connected with the “big pond” of the experimental data. The complete workflow to integrate whole available knowledge from independent small sciences needs the novel computational framework and connectivity platform (Kitano *et al.*, 2011). Recent advances in the development of such platforms include Garuda (Ghosh *et al.*, 2011), Galaxy (Goecks *et al.*, 2010), GenomeSpace (Qu *et al.*, 2016), and Taverna (Oinn *et al.*, 2004).

All these bottom-up and top-down efforts contributing to whole-cell modeling have opened up opportunities for the systems-level understanding of cells to assess the mechanism of how cell behavior can advance the evolvability of life.

Glossary

Complexity science A field of study aiming at defining methods and tools to assess and predict the dynamics of a complex system using a holistic approach.

Complex system A hierarchical self-organized system with a large number of components characterized by non-linear connections. In such systems order is an emergent property of its internal microscopic dynamics.

Computation All steps necessary for a digital computer to solve a problem. A computation transforms the input, i.e., the definition of a problem in mathematical terms, into outputs, i.e., the solution of the problem in terms of values of some of the problem's variables.

Dynamics Area of classical mechanics concerned with the study of forces and torques and their effect on motion. More

in general, the dynamics of a system describes the trajectory of the constituting variables in a proper mathematical space.

Mathematical modelling Description of a natural systems by means of the mathematical language that is then suitable for transformations and other mathematical treatments to find non-trivial relations among system elements.

Networks Graphical description of the relations among entities that is then viable to mathematical treatments such as those of graph theory.

Simulation computer recreation of the dynamics of natural or artificial systems.

Stochasticity The presence of something that is not deterministically determined. In mathematics, it is used to indicate the use of a random element in the description of a system.

Introduction

The recent wide availability of experimental high-throughput omics data (genomics, proteomics, metabolomics, etc.) is fostering the development of theoretical biology. This data is analysed by established bioinformatics tools that have been developed in the past decades as well as by novel approaches devised at a great pace by the community. However, the results of such analysis are in some cases inconclusive and further investigation is necessary to make sense of it. This is when mathematical, statistical and computational approaches such as modelling and simulation come into play. This article briefly describes few but well-representative methods that have been used to this purpose in the last couple of decades.

Quantitative modelling of biological phenomena comprise all methods borrowed by other quantitative or *exact* disciplines such as physics, mathematics, computer science or engineering, that are nowadays used to tame the biological complexity. Given the enormous diversity found in biological systems, it is in general difficult to obtain quantitative estimation of parameters of interest and often the results are dependent on the modelling assumptions. Therefore, the methods range between the two extremes of being completely qualitative to perfectly quantitative. Qualitative methods provide an approximate explanation of what is going on in the studied system without being able to estimate values precisely or give clear indications about how to influence the system (Saadatpour and Albert, 2016). On the other hand quantitative methods provide answers to specific questions with numbers, that is, with something that is readily useful in real practice without the need of further (complex) transformations or assumptions (Mogilner *et al.*, 2006).

The usefulness of computational models in systems biology has been pointed out in many recent literature review articles (Bartocci and Lió, 2016; Fisher and Henzinger, 2007; Ji *et al.*, 2017; Machado *et al.*, 2011; Materi and Wishart, 2007). This article, however, aims at providing an informal and not exhaustive introduction to the main computational modelling approaches adopted in systems biology. Besides the classical differential equation approach, this paper presents other computational dynamic approaches such as Petri nets, Boolean networks, cellular automata, agent based models, and the statistical methods of Bayesian networks and formal systems such as process algebras.

Background/Fundamentals

Mathematical modelling has a long tradition and is central to most disciplines of science and engineering. It characterizes the scientific effort in describing nature in quantitative terms. Newton's work which was published in the 17th century, is probably the most striking example of application of the concepts of calculus to describe a physical system (i.e., the motion of planets in terms of differential equations). A model is, today as then, a mathematical description of the elements of a process and the ways in which they influence each other. The mathematical description, sometimes amenable of symbolic transformations, leads to a formulation of the "solution" which reveals aspects of the structure and dynamics of the system that are not plainly recognisable at a first sight. Mathematical (now computational alike) modelling is an iterative process which goes from the real-life phenomenon to the virtual mathematical object called the "model" that produces "results" in terms of how it behaves in hypothetical scenarios.

Fig. 1 Mathematical or computational modelling is an iterative process which involves the translation of the most significant characteristics of the real problem into a mathematical formalism amenable of computation (or analytical treatment) to produce results that are then interpreted to be translated back to reality. Those need then to be compared to the real system to be validated so to show the correctness and even usefulness of the model. If this is not the case, the model is improved and the whole cycle is repeated.

To be scientifically sound, these results should be compared to actual data that were produced by the real-life phenomenon and were not used to build or infer the model yet. This comparison, which is called model validation, usually identifies shortcomings or problems in the model, advocating some model adjustment, hence the iterative scheme described in Fig. 1.

This practice is not different when the system under consideration comprises life. On one side, we have a biological system we wish to understand and on the other side we have a model corresponding to our understanding of the real system that allows us to perform analysis and testing of hypothetical scenarios. This is for instance the case of a model describing the pathogenesis of a disease permitting to test different therapeutic interventions thus enabling the search for the most successful treatment options.

Models can be broadly classified according to their structure. A first important distinction to be made relates to whether or not time is one of the variables of the model. A *dynamic* model accounts for time-dependent changes in the state of the system whereas *static* models only consider the system at equilibrium. Static models are often used to describe the invariable relations among objects such as, for instance, proteins, metabolites or genes. A subfield of systems biology called network biology deals with such descriptions in terms of graphs or networks. Dynamical models allow for “forecasting” hypothetical scenarios and are quite valuable, for instance, in finding optimal clinical interventions in modelling of disease progress.

Another distinction concerns the involvement of the concept of randomness among the elements of the model. A model is *deterministic* if the current state of the model is uniquely determined by the model parameters and its previous states. That is, given an initial state, a deterministic model always follows the same “trajectory”. In contrast, the trajectories of a *stochastic* model may vary depending on the randomness present, in other words, by the variance of the stochastic variables that are therefore not described by unique values, but rather by probability distributions.

A third important classification criterion is the structure of the space from which the variables of the model take on their values. A variable is called *discrete* if it takes on values from a countable set (finite such as the set $\{0,1\}$ or infinite such as the set of integers), otherwise, it is called *continuous*, that is the case when its values can be arbitrarily close real numbers. If all variables are discrete then the model is said to be discrete. On the other hand, if all variables stand for continuous values then the model is continuous. Finally, hybrid models contain both continuous and discrete components. For instance a model of bacterial growth could represent with $n(t,x)$ the number of bacteria at time t in a certain volume at position x with time and space continuous but state n discrete.

In the following sections, we briefly illustrate different mathematical or computational modelling paradigms classifiable according to the mentioned criteria above. We leave to the reader the leisure of recognising each of them. The paragraphs also report examples of application of the methodologies in the biomedical field with the hope to convey the message of the convenience of quantitative reasoning in these fields. References of relevant works are provided and further references for interested readers are provided at the end of the article.

Differential Equations

Ordinary Differential Equations

To our knowledge one of the earliest work in the literature that used differential equations in biology was the influential and controversial paper by Daniel Bernoulli which was published in 1760. Using a simple model of differential equations, Bernoulli was able to show that the long-term benefits of inoculation outweigh the risk of immediate death as it may lead to increasing the life expectancy. For more information about the original Bernoulli’s model see Chapter 4 of Bacaër (2011), and, for recent work on Bernoulli’s model, see Dietz and Heesterbeek (2002).

For a given biological system of interacting species (substances, chemicals, ...) where their concentrations are functions of only one variable (time, age, or cell size,...), an ordinary differential equation (ODE) model of the system is basically a collection of equations, one for each species, describing the rate of change in the concentration of the species, with respect to the variable, in terms of the concentrations of other species in the system, see Fig. 2, which presents the well-known Lotka-Volterra or predator-prey model of two interacting quantities x (prey) and y (predator) with the initial concentrations being x_0 and y_0 , respectively. This

Fig. 2 Differential equations models exemplified in a predator-prey relation. The Petri-nets modelling paradigm is very generic and apt to model concurrency not just in biological systems. It consists in tokens moving among places through transitions epitomising conditions. Boolean networks have been conceived to describe gene regulation but are general enough to be applied to other field of science well. Bayesian networks are statistical methods which allow to estimate the strength (probabilistically speaking) of a relation among two objects such as genes, give a set of data.

model has four parameters, namely A , B , C , and D . For more information about predator-prey models, see Chapter 13 of [Bacaër \(2011\)](#). A similar but more specific example of ODE system applied to clinic is those in [Dell'Acqua and Castiglione \(2009\)](#) and [Jarrah et al. \(2014\)](#) about modelling muscular dystrophy.

Values of the parameters of a model are determined based on the available data and using any of several parameter estimation methods such as Genetic Algorithm, Particle Swarm, Simulated Annealing, Steepest Descent, to name few ([Moles et al., 2003](#)) and multiple shooting method for stochastic systems ([Peifer and Timmer, 2007](#)). For biochemical networks, the parameters could be assumed to be of one of two forms depending on the underlying kinetics: mass action or Hill function which includes Michaelis-Menten as a special case. While Mass Action (polynomial form) is appropriate when the reaction rate among species is proportional to the probability of the collision of the particles of the species, the Hill function in general is used in enzyme kinetics as well as protein's activation or inhibition.

Regardless of the optimization method, parameter estimation is probably the hardest step in the ODE approach for modelling biological systems ([Chou and Voit, 2009](#)) mainly due to the large number of species being modelled, their nonlinear interactions, and the fact that available quantitative data are limited. Yet the ODE approach is probably the most popular among all, mainly due to its solid and old mathematical foundation as well as its huge success in modelling a variety of biological systems at all levels; such as the famous population dynamic model predator-prey, Hodgkin-Huxley model of excitable neuron ([Hodgkin and Huxley, 1952](#)), and gene regulatory network of yeast cell cycle ([Tyson and Novák, 2015](#)) to name a few.

There are many different variations of the ODE approach, in particular, stochastic ODE ([Bachar et al., 2013](#)), delay ODE ([Parmar et al., 2015](#)). Also the S-systems ([Savageau, 1988](#)) is a special class of ODE models that assumes a specific structure of the system.

There are several general ODE solvers as well as specialized standalone software that can be used for parameter estimations and solving ODE. The standalone software CellDesigner ([Matsuoka et al., 2014](#)) and COPASI ([Hoops et al., 2006](#)) can be used for the modelling and simulation of biochemical networks and both have most of the mentioned methods and features above.

One of the main limitations of the ODE approach is the fact that it assumes that the species are well-mixed, and hence it cannot be used to properly model a system that is space-dependent. This can be easily resolved when using partial differential equations.

Partial Differential Equations

This approach enables modelling interacting species as functions of more than one variable. In particular, a partial differential equation (PDE) represents the change in the concentration of a substance with respect to not only time, as most ODE models, but also to other variables such as place (spatial coordinates), age and size of a cell.

Alan Turing developed a simple PDE model of two diffusible and interacting chemicals, and hence the name reaction-diffusion model, and he used the model to explain the pattern formation in the developing animal embryo ([Turing, 1952](#)). Since then, the reaction-diffusion model has been the basis of most PDE methods for the PDE modelling and simulation of complex biological patterns ([Kondo and Miura, 2010](#)). For a comprehensive treatment of the subject, see [Murray \(2003\)](#).

Modelling methods using the PDE approach have been developed to study various kinds of biological systems at all levels; such as ion singling (Ramay *et al.*, 2010), chemotaxis-driven migration of T-cells toward infection sites (Vroomans *et al.*, 2012), and climate change (Goosse *et al.*, 2010) as well as weather prediction (Steppeler *et al.*, 2003).

Similar to the ODE approach, solving PDE equations is not easy and is usually done using numerical techniques (Tadmor, 2012). Furthermore, methods for the parameter estimations of PDE models have recently been developed using different approaches such as least squares method (Muller and Timmer, 2002) and Bayesian methods (Xun *et al.*, 2013).

Difference Equations

In *Liber Abaci*, which was published in 1202, Fibonacci investigated how fast rabbits could breed. Assuming ideal environment, he developed a model for the number of rabbits using a difference equation and produced the famous Fibonacci's sequence: 1, 1, 2, 3, 5, 8, 13, 21, It is worth mentioning that Fibonacci's sequence has appeared in other areas within as well as outside biology. Fast forward to the 20th century, difference equations models of various biological systems are ubiquitous, in particular, the difference equations approach provides a discrete version of population biology in general (Cull *et al.*, 2005). Also, finite difference equations are used to develop numerical methods for solving ODE and PDE systems (Sewell, 2006). Furthermore, difference equations approach provide a generalization as well as a mathematical framework for cellular automata (Itoh and Chua, 2009) and other finite discrete methods. See the classical textbook (Elaydi, 2005) for more information on the theory of difference equations, and Allman and Rhodes (2004) and Cull *et al.* (2005) for examples of how the difference equations approach is used to model several biological systems such logistic growth and phylogenetic trees. Difference equations are best for studying discrete-time, population dynamics with stochastic features (Witten and de la Torre, 1984).

Petri Nets

Petri nets (PN) are directed bipartite graphs with nodes belonging to one of the two sets called states (also called places) and transitions (see Fig. 2). They were conceived by Carl Adam Petri in 1962 to describe chemical reactions (Petri and Reisig, 2008). Indeed, the states indicate substances and the transitions the reactions. Nodes identifying states are filled with tokens to indicate that the relative substance is present (alternatively, that the substance is present in sufficient concentration to allow the reaction to take place). When a transition has more than one incoming arcs (called *take arcs*) linked to corresponding states, those states all have to contain sufficient tokens to allow the transition to fire, meaning that the reaction takes place and the token is moved ahead in the states linked downward the exit arcs (called *give arcs*) (see Fig. 2). In this manner, the states code for conditions that need to be satisfied for a transition (or more generically an action) to take place. The flexibility of this modelling formalism allow its use to describe concurrent process in distributed systems. It has indeed been extensively used in computer science to describe distributed processing. In systems biology, Petri nets and its variants, developed to remove constraints such as the use of a discrete number of tokens (i.e., the coloured PN), or the use of deterministic transitions (i.e., the stochastic PN), have been employed to model biochemical networks (Chaouiya, 2007; Goss and Peccoud, 1998; Srivastava *et al.*, 2001) such as metabolic processes (Simao *et al.*, 2005) and cell signalling (Li *et al.*, 2007). The description of a biological process such as those at the molecular level just mentioned, is quite straightforward with PN. Moreover, given the intrinsic account for the temporal scale, such formalism is quite appealing for biologist that can analyse, mainly in a qualitative fashion but in principle also in a quantitative manner, complex biological phenomena by answering what-if questions such as "what will happen if the production of a molecular compound is inhibited?"

Boolean Networks

Boolean networks (BN) have been introduced by Kauffman in 1969 to model gene regulation (Kauffman, 1969, 1993). They represent genes as nodes of a graph with two types of arcs, activation or inhibition, denoting respectively an activation of, say, gene g_2 subsequent to the activation of gene g_1 , and inhibition, indicating the capacity of an express gene to block the transcription of another gene (see Fig. 2). The model describes the temporal evolution, carried out in discrete steps, of the active/inactive states of the set of genes. At each time step the state of each gene is determined by a Boolean logical rule which is a function of the state of the genes which impinge upon it (i.e., its regulators). For instance, for the network in Fig. 2, the Boolean formula for node g_4 could be $g_4(t+1) = g_3(t) \text{ AND } g_5(t) \text{ AND NOT } g_2(t)$.

The state of the genes can be updated all at once (synchronous update) or one at a time with a specified or unspecified order (asynchronous update). The two evolutions are not equivalent with the latter being much more complex to compute than the former. The space of the possible trajectories of the set of gene-expression grows exponentially with the number of genes thus its exploration to determine the dynamical properties of the BN becomes quickly unfeasible. On the other hand, the analysis of network properties such as its robustness or the steady-states of its dynamics which identify specific biological functions, are exactly the reward of using such models (Li *et al.*, 2004).

Boolean networks are generally inferred from time-series of gene expression data (D'haeseleer *et al.*, 2000) or are constructed by expert manual curation from literature data (Pedicini *et al.*, 2010). Boolean networks have also been employed to model signalling pathways (Saez-Rodriguez *et al.*, 2007). For these biological applications the limitation of the two-values logic has been removed in the multi-valued extension (Schaub *et al.*, 2007). Moreover, to account for the presence of noise and uncertainty, the stochastic extensions of probabilistic Boolean networks were introduced (Shmulevich *et al.*, 2002).

Bayesian Networks

A Bayesian network is a statistical model describing a set of variables and their conditional dependencies via a directed acyclic graph (see Fig. 2). The nodes of the network represent random variables whereas the edges stand for dependencies between couple of variables. The value of each variable is determined by a probabilistic function of the variables associated to the nodes than impinges upon it.

Bayesian networks were introduced by the work of Pearl (Pearl, 1988) as generic probabilistic methods to infer relationships among variables given a set of data. In fact, based on the formula from Bayes, there exist learning methods to infer the probability parameters also in case of incomplete data. Data coming from gene regulation activity provide a natural example of applicability of Bayesian networks. In this case the nodes-variables are the expression levels of the genes and the probabilistic relationships identified by the edges are estimated by means of the inference algorithms (Friedman, 2004). Data from signalling networks is amenable to this representation and analysis (Sachs *et al.*, 2005). The disadvantage due to the inability to model feedback loops present in biological networks has been removed in an extension called dynamic Bayesian networks (Husmeier, 2003; Kim *et al.*, 2003; Zou and Conzen, 2005).

Microscopic Ab-initio Models

Models in this category are usually discrete (both in time and space) dynamic models that aim to simulate/address biological problems for which spatial properties strongly affects the resulting dynamics. Discrete models are better suited to capture the discrete nature of individual cells than continuous models, especially when dealing with complex systems involving many variables such as sets of cells in different stages of their life cycle or distinguishable by the affinity of their receptors for different antigens. Cell-based models such as cellular automata, cellular Potts and agent-based models are able to represent the behaviour and interactions of each individual cell in a biological system. In these models, the macroscopic dynamics of a system is an emergent property of the microscopic interactions and for this reason they are considered bottom-up modelling approaches.

The Ising model (1925) is the simplest theoretical model of ferromagnetism used to study ferromagnetic phase transitions and is considered by many the precursor of cellular automata and agent based models. In the Ising model each magnetic dipole moment of atomic spins is represented as a discrete variable characterized by one of two states ($+1$ or -1) and arranged on a lattice. The interactions between spins are local and each spin is allowed to change synchronously based on the spin state of its neighbours.

Cellular Automata

Cellular automata (1940s) are a general computational model characterized by discrete space, state, and time (Ilachinski, 2001; Toffoli and Margolus, 1987; Wolfram, 2002) inspired in the first half of the 20th century by the work of John von Neumann (von Neumann, 1966) and Stanislaw Ulam (Ulam, 1952). A cellular automata model is a discrete dynamic system defined by a grid (a finite metric space), a finite set of possible cells states, a function describing the neighbourhood of a cell (the set of cells influencing the one under consideration) and a transition function determining the state of a cell in the next time step depending on the state of the cells in its neighbourhood (see Fig. 3).

Classical cellular automata are synchronous (all cells update their state simultaneously thus the grid state is independent from the order of update of the grid), local, and homogeneous. Many modifications of the classical model exist: asynchronous automata, heterogeneous automata, non-uniform cellular automata, stochastic automata and many others such as movable cellular automata (Psakhie *et al.*, 1995), Brownian cellular automata (Lee and Peper, 2010).

Cellular automata have been extensively used as a modelling paradigm in biology (Ermentrout and Edelstein-Keshet, 1993). Some applications include the study of idiotypic B cell proliferation in the human immune system (De Boer *et al.*, 1992) or the dynamics of infectious diseases (Zorzenon dos Santos and Coutinho, 2001).

Cellular Potts models, also known as Glazier Graner-Hogeweg models (Graner and Glazier, 1992; Glazier and Graner, 1993), are an evolution of cellular automata in which each cell occupies more than one lattice site or pixel. For this reason, each cell has a shape which varies over time as a function of a Hamiltonian representing the adhesion energy of the cell and other mechanical constraints such as surface-area-to-volume ratio. One of the most known framework for cellular Potts model is CompuCell3D (Chaturvedi *et al.*, 2005; Popławski *et al.*, 2008) which has been used in several different applications, from anatomical and pathological conditions of tissues and organs to models of single-species and multi-species biofilm growth. In this hybrid framework, the mechanical properties of the cell membrane can be integrated with continuous models of reaction-diffusion dynamics and models of intracellular signalling dynamics achieving a complete and realistic multi-scale model of a complex biological system.

Agent-Based Models

Agent-based models (ABM) are an evolution of the simpler cellular automata model in which each agent is an autonomous decision-making entity interacting on the basis of a given set of rules which are not necessarily identical (Bonabeau, 2002; Gilbert, 2008). Strictly speaking, ABMs are not discrete in time and space as they are exemplary of hybrid systems where discrete time variables are combined with continuous state-space ones. Nevertheless, in their applications to biology and medicine and with the purpose to speed up execution on a computer, agents are usually placed on a structure (a two dimensional or three-dimensional lattice representing real-world spatial environment such as a lymph node or a complex network representing social contacts or sexual interactions) that defines the couples or groups of agents that are going to interact at a given time. Agent-based models have

Fig. 3 Cellular automata and agent-based models represent entities individually. These evolve according to defined rules whose complexity range from rather simple (often Boolean) functions in cellular automata to sophisticated algorithms for the agents' behaviour in agent-based models. Furthermore, as an example, one can construct complex hybrid models embedding Boolean networks in agents representing biological cells to set up the rule for its differentiation. Pi-calculus is a different approach used to formally describe a complex system such as a chemical reactor and to conduct (in the case of stochastic calculi, e.g., stochastic k-calculus) simulations much like in the previously described methodologies.

been used to study many different problems. For instance, they have been used to simulate HIV or gonorrhoea epidemics where agents represent individuals part of a sexual contact network (Mei *et al.*, 2011) or to describe the population dynamics of ecosystems in which each agent is an animal or a plant. They have also being used to model the intracellular dynamics phenomena in which agents are viral particles moving within the cytoplasm of an infected cell. Finally, they have been extensively used to describe the dynamics of the immune system. In this case the agents represent all the entities involved in the immune response to a pathogen such as immune cells, epithelial cells, bacteria, viral particles etc (Castiglione and Celada, 2015).

Several frameworks can be used to implement agent based models: NETLOGO, FLAME, MASON, JASON and REPAST are some of the most versatile and supported frameworks.

Process Calculi

The design of a computational implementation of any biological system starts from the knowledge of the living system under consideration and by abstracting its main characteristics. This task is fulfilled by means of some formal method such as those describing the syntax of a computer language. The most striking feature of biological phenomena that is difficult to capture in symbolic formal methods is concurrency. Formal systems, therefore, need to be able to fully denote such biological complexity or otherwise turn out inaccurate and eventually useless.

Process calculi or process Algebras (PA) are formal systems devised to easily express parallel computations and their properties (like Church's lambda-calculus introduced to express Turing computable arithmetic functions). The most successful system was Milner's pi-calculus introduced to express interactions between concurrent processes (Milner, 1989). PAs share some similarity with formalism used in the description of chemical reactions (see Fig. 3 for the example of the phosphorylation/dephosphorylation reaction expressed in pi-calculus). This was precisely established with the introduction of the Chemical Abstract Machine or CHAM (Berry and Boudol, 1992), where the states of the parallel machine are chemical solutions and molecules can interact according to reaction rules.

Biological phenomena involve millions of moving particles in any single cell while millions of cells form tissues which transport substances, transform energy use signals, etc. Notably, biological systems process information necessary to the organization of life by the same mechanisms they use to processes any other element, like the nutrients. Process algebras are considered suitable formalisms to model these kinds of systems because the transmitted information is processed *concurrently* and

asynchronously. Moreover, part of essential transactions which happen in biological systems are inherently computational and therefore they can be expressed with formal languages used to describe concurrent processes.

While representing biological systems with PAs, several researchers realised that there was a missing dimension: quantitative aspects were neglected in the description of the interaction rules. The stochastic pi-calculus (Priami, 1995) was an enriched Milner's formalism with a quantitative context semantics giving access to the world of simulations of biochemical processes (Regev *et al.*, 2001; Priami *et al.*, 2001). Further developments were obtained by deriving new formal systems by adding missing features to PAs: bio-ambients (Cardelli and Gordon, 2000) and brane-calculi (Cardelli, 2005) allowing compartments, the kappa-calculus (Danos and Laneve, 2004) with the specific purpose of representing protein interactions.

The prominent aspect to remark regarding the convenience for using this approach in describing biological processes is that it enables, for instance, the syntactic and semantic comparison (hence prompt translation of the properties of the first to the second system) between two concurrent systems once formalised with a PA or to build incrementally complex process from a multitude of elementary processes being either independent or interrelated.

Closing Remarks

Computational methods are used to make sense of the vast amount of data produced by experimental biology high throughput technologies and, importantly, to “fill the dots” where data is incomplete in revealing the underlying structure or in describing the temporal evolution of the system under study. Mathematical or computational modelling methods are applied and even developed anew to analyse such data, to dig information out of it, to discover structures, to generalize conclusions, to provide scenarios to choose from, etc. The accuracy of these computational approaches ranges from low (that is when we call the approach qualitative) to high (i.e., that is quantitative) depending on the data availability.

The methodologies range from classical differential equations to more unconventional agent-based simulation, passing through process algebra and statistical approaches. These models have shown to be promising if not even concretely useful in some cases, revealing biological aspects of the phenomena under consideration which were impossible to see just by inspecting the data. Vice versa, biology is providing a number of challenging problems to appraise the methods themselves, encouraging computational scientists to extend and improve existing methodologies (Machado *et al.*, 2011).

One of the greatest challenge in this respect is the construction of multi-scale models embracing the wide range of time and length scales of biological phenomena. Whereas few modelling techniques though theoretical able to handle different scales (e.g., process algebras or Petri nets), their practical use is impaired by the combinatorial explosion of variants eventually leading to computational intractable problems. In this case the obvious trick is to combine two or (rarely) more approaches that have their strength in different time/length scale into a unified hybrid multi-scale system (Fisher and Henzinger, 2007; Bortolussi and Policriti, 2008; Fromentin *et al.*, 2010). This is for instance the case of agent-based models of cellular systems where each agent/cell is equipped with a system of ordinary differential equations or a Boolean network to describe the regulatory network among genes driving its behaviour (see Fig. 3).

Computational biology is a flourishing field of applied mathematics and computer science. Only in the past two decades the collective effort of computational scientists combined with the expertise of field biologist have produced a number of open-software that offer the model techniques described in this brief article to analyse experimental data and/or to simulate hypothetical scenarios. Review papers such as Bartocci and Lió (2016) offer a nice view of what is available at the time of that publication. There is no reason to believe that such vigorous effort in the systems biology community will grow smaller, but rather just the opposite, new tools will be available soon, either as improvements of existing methodologies or able to exploit and combine different formalisms and modelling paradigms to provide powerful platforms for the analysis of the ever increasing experimental and diagnostic data.

Biographical Sketch

Filippo Castiglione is researcher at the Istituto per le Applicazioni del Calcolo of the National Research Council of Italy and adjunct professor of Computational Biology at the Department of Mathematics and Physics of Roma Tre University. He graduated in computer science at the University of Milan, Italy, and got a PhD in Scientific Computing at the University of Cologne, Germany. He has been PostDoc at the Institute for Medical Bio-Mathematics in Tel Aviv, Israel and visiting research fellow at the IBM - T.J. Watson Research Center, Yorktown Heights (NY), at the Department of Molecular Biology at Princeton University and at the Department of Cell Biology, Harvard Medical School, Boston. Filippo has published one book and about 100 reviewed research papers among journals, books and conferences proceedings. He is the main author of the C-ImmSim agent-based simulation model of the immune system. Filippo has been involved as principal investigator in two EU-funded projects of the ICT for Health of the 6th Framework Programme (FP6) and has coordinate a project of the FP7. His research interests range from the study of complex systems to the modeling of biological systems, machine learning and high-performance computing.

Emiliano Mancini is programme developer on Health Systems Complexity at the Institute for Advanced Study in Amsterdam, where he coordinates the research in various academic disciplines for interdisciplinary research projects. In this role, he also engages private companies and stakeholders for the valorisation and utilization of these academic projects as well as collaborate on the strategic plan for the growth of the Institute. Emiliano obtained his Master degree in Physics at University of Rome Tor Vergata and a PhD in Computational Science at University of Amsterdam simulating infectious diseases (HIV and H1N1) using agent-based modeling. As a postdoc Emiliano has worked between University of Amsterdam and the Nanyang Technological University in Singapore on modeling the dynamics of several complex biological systems. He worked as a consultant or team member of several start-up companies and has been involved in the development of a clinical decision support platform for HIV treatment and on a non-invasive continuous glucose meter funded by SMART-MIT. Emiliano was also responsible for the organization and supervision of several experiments on crowd dynamics for the Kumbh Mela Experiment: an Indo-Dutch project to study the Kumbh Mela, the largest religious event in the world.

Marco Pedicini is professor of Computer Science at the Department of Mathematics and Physics of Roma Tre University. He received his Ph.D. in Mathematics (Mathematical Logic and Theoretical Computer Science) from the University of Paris 7 in 1998. He was researcher at Italian National Research Council (CNR). Since his PhD thesis, Marco has developed ideas in TCS and his interests include logic in computer science, cryptography, computer security, parallel and distributed computing, computational methods for systems biology, computational number theory, and more recently quantum computing. Although his whole activity could be classifiable in TCS it finds in interdisciplinary research its own specificity. Interactions with other disciplines are the key to evaluate his scientific activity: in fact, he developed a very special kind of expertise while coping deep theoretical results with practical issues in advanced applications in collaboration with colleagues of different disciplines. Marco has published 30 scientific papers, many of them in leading international journals and selective peer reviewed conferences. In order to witness a broad area in Marco interests, these papers not only appeared on top conferences and journals in logic for computer science but also on top journals covering application of computer science to biology and medicine.

Abdul Salam Jarrah is a Professor of Mathematics and a faculty member of the Master of Science in Biomedical Engineering Programme at the American University of Sharjah (AUS) in the United Arab Emirates. Before joining the AUS in 2009, he was a senior research scientist at the Virginia Bioinformatics Institute and Affiliate Assistant Professor at the Department of Mathematics in Virginia Tech, USA. Prior to that, he was as an Assistant Professor of Applied Mathematics at East Tennessee State University, USA. In addition, Abdul was a member of the Mathematical Sciences Research Institute at Berkeley, USA from August 2016 to January 2018. He received his PhD in Mathematics from New Mexico State University in 2002. His current research interests span many areas of mathematics including discrete dynamical systems, discrete homology theory of graphs, computational algebra, and their applications in biology, especially the modeling and simulation of biological systems. He has made several contributions to these fields through many publications in international journals.

Data Formats for Systems Biology and Quantitative Modeling

Standards for Computational Systems Biology

Standards support communities with a basis for mutual understanding and information exchange and thereby shape our everyday life. Common standards are indispensable for collaborative work. An example is the Baltimore fire in 1904, when more than 1500 buildings were destroyed even though fire departments from Washington, Philadelphia, New York, and other towns provided aid, as they found their hose couplings did not match the city's fire hydrants due to a lack of standardization. This reduced the impact of help significantly and led afterwards to a national standard for hose couplings and fire hydrants in the USA (Seck and Evans, 2004). A similar breakdown of collaborative work due to a lack of standardization, however, could happen in any field that requires interfacing between different parts, especially in research fields such as in the modern life sciences with their increasing flood and complexity of data and all the vast variety of technologies that have to be brought together like in a jigsaw puzzle.

Standardization of data and their documentation is all the more important for highly interdisciplinary and collaborative fields such as systems biology and systems medicine, where computational models are created that can assist with understanding, describing, analyzing, and prediction of biological systems and their functions. Over the last 20 years computational modeling has grown from a niche activity in systems biology into a standard tool in the life sciences, as documented by the increasing number of published models stored in public model repositories (Li *et al.*, 2010; Yu *et al.*, 2011). Model-driven design, testing, analysis, and optimization of biological systems are performed computationally by integrating a variety of heterogeneous data together within mathematical frameworks in order to understand and predict the complex and dynamic, often nonlinear molecular interactions within cells, as well as the interplay of cells within tissues, organs, organisms, and beyond that even the interaction of different organisms in whole biological ecosystems. Because of the interdisciplinary approach in systems biology these datasets are coming from different sources, derived from different experimental setups, and correspond to various technologies applied to collect the data.

A computational model in systems biology, thus, typically relies on a collection of varied data, which can include, for example, data from genomics, transcriptomics, proteomics, or metabolomics experimental setups, reaction kinetics information, and imaging data. This requires a consistent structuring and description of data and computer models with their underlying experimental or modeling processes, comprising the standardized description of applied methods, biological material and workflows for data processing, analysis, exchange, and integration (e.g., into computational models), as well as of the setup, handling, and simulation of the resulting models. Hence, standards for formatting and describing experimental data, applied workflows, and computer models have become important, especially for data integration across the biological scales for multiscale approaches. Such a consistent documentation based on standards ensures that the data and corresponding metadata (data describing the data and its context), as well as models, methods, and visualizations are structured and described in a "FAIR" manner: Findable, Accessible, Interoperable, and Reusable (Wilkinson *et al.*, 2016).

Systems biology standards are not static but develop and evolve with the progress of science and technology. A major challenge is to harmonize the standardization efforts in the different fields that refer to different approaches and technologies and to make the corresponding standards interoperable. The standards used for encoding and annotating models and related data are designed by experts with an understanding of what key information will comprise the outcome of an experiment, and how this information is best structured and formatted. The development of such standards for systems biology typically occur at a grassroots level driven by the corresponding scientific communities themselves with their need for exchanging data and models. The COMBINE (see "Relevant Websites section") network ("COMputational Modeling in BIOlogy NEtwork" (Hucka *et al.*, 2015b; Myers *et al.*, 2017)), for example, is a consortium of groups involved in the development of open community standards and formats used in computational modeling in biology. It was formed in 2009 following the observation that many standardization efforts shared similar goals and sometimes even involved the same individuals. The network helps foster greater interaction and awareness of the activities in different standards' development, which encourages the federated projects to develop standards that are more likely to be interoperable and less likely to overlap substantially than if the efforts proceeded separately. Building on the experience of mature standards, which already have stable specifications, software support, user bases, and community governance, it also supports emerging efforts aimed at filling gaps or addressing new needs in the overall interoperability landscape. The COMBINE initiative published the first collection of systems and synthetic biology standards as a special issue of the *Journal of Integrative Bioinformatics (JIB)* in 2015 (Schreiber *et al.*, 2015). Since then a regular special issue of *JIB* serves as both an overview of existing standards as well as an update of the current state of standards in the domain (Schreiber *et al.*, 2016, 2018).

Given the diversity of research topics in computational biology, and the different facets of modeling, multiple specific standards, with particular purposes, are needed – also beyond the COMBINE standards – in order to formalize and serialize the data (Stromback *et al.*, 2007; Klipp *et al.*, 2007). In the following, several standards for specific tasks in systems biology and related fields will be introduced, in order to provide examples for typical workflows and the standards that can be applied therein.

Standards for Data Used for Model Construction

The first step in generating a model is collating the datasets that need to be integrated into the model. This task heavily relies on the datasets being formatted and annotated correctly. Reporting and annotation checklists, or “minimum information guidelines” as they are often called, for different types of data derived from a big variety of laboratory technologies are readily cataloged for the biosciences as part of MIBBI (Minimum Information for Biological and Biomedical Investigations (Taylor *et al.*, 2008)). Such guidelines are widely accepted for some data types, for example, for the description of microarray experiments (MIAME, Minimum Information About a Microarray Experiment (Brazma *et al.*, 2001)), genome sequences (MIGS, Minimum Information about a Genome Sequence (Field *et al.*, 2008)), or proteomics experiments (MIAPE, Minimum Information About a Proteomics Experiment (Taylor *et al.*, 2007)). The FAIRsharing community makes a wide range of minimum information checklists available for researchers in the MIBBI FAIRsharing collection (see “Relevant Websites section”). Finding comprehensive lists about formatting standards for different types of data can be difficult, and not all formatting standards or annotation checklists are still maintained, or fully usable. To reduce the time required to identify standards that are maintained and usable, FAIRDOM (see “Relevant Websites section”) maintains a FAIRsharing collection of formatting standards, and checklists that are known to be actively used within the systems biology community (see “Relevant Websites section”). This collection is based on a community survey commissioned by Infrastructure for Systems Biology Europe (ISBE) (see “Relevant Websites section”) in 2015 (Stanford *et al.*, 2015).

Experimentally obtained kinetic data that describe the dynamics of biochemical reactions (e.g., metabolic or signaling reactions within a cellular network), for instance, can be obtained from databases such as SABIO-RK (Wittig *et al.*, 2012) (see “Relevant Websites section”). This manually curated database contains data that are either extracted by hand from the scientific literature (Wittig *et al.*, 2014) or directly submitted from laboratory experiments (Swainston *et al.*, 2010). The database content includes kinetic parameters in relation to the reactions and biological sources, as well as experimental conditions under which they were obtained, and is fully annotated to other resources, making the data easily accessible via web interface or web services for integration into the computational models. Through export of the data (together with its annotations and SABIO-RK identifiers for tracing back to the original dataset) in standardized data exchange formats like SBML (Systems Biology Markup Language) (Hucka *et al.*, 2003) this allows the direct data integration into models.

Standards for Structuring Models of Biological Systems

Model representation formats standardize the structured encoding of biological models. Examples mainly used for models consisting of molecular entities and describing their interactions and dynamical interplay include:

- SBML (Systems Biology Markup Language) as standardized interchange format for computer models of biological processes (Hucka *et al.*, 2003; Hucka *et al.*, 2018).
- CellML, a standard format to store and exchange reusable, modular computer-based mathematical models (Cuellar *et al.*, 2003).
- NeuroML (Neural Open Markup Language), which allows standardization of model descriptions in computational neuroscience (Gleeson *et al.*, 2010).

All three are based on XML (Extensible Markup Language) (see “Relevant Websites section”), a markup language that defines a set of rules for encoding documents in a format that is both human-readable and machine-readable. These formats represent the structure of a model (e.g., the biochemical network) and enable annotation of the model to better convey a model's intention. Here the focus will be on two of the most widely used standards, SBML and CellML.

SBML (Systems Biology Markup Language)

The Systems Biology Markup Language (SBML) (Hucka *et al.*, 2003) is a machine-readable representation format for computational models in systems biology. This format began its development in 2000 as a way of encoding models for the exchange between modeling software platforms and ensuring longevity of the models beyond the software used to create it. The evolution of SBML proceeds in stages in which each “Level” is an attempt to achieve a consistent language at a certain level of complexity. The current version of SBML is Level 3 Version 2 (Hucka *et al.*, 2018). SBML Level 3 is modular, with the core usable in its own right and Level 3 packages being additional “layers” that add features to the core. By itself, core SBML Level 3 is well suited to representing such things as classical metabolic models and cell signaling models, involving well-mixed substances and spatially homogeneous compartments where they are located. Other model types can also be expressed using SBML's core constructs, but SBML Level 3 packages that extend the core and are optional in their use, add more natural support for such types and additional model features, such as visualizations (Gauges *et al.*, 2015), constraint-based models (Olivier and Bergmann, 2015; Olivier and Bergmann, 2018), hierarchical model composition (Smith *et al.*, 2015), or grouping of elements (Hucka and Smith, 2016).

SBML models are decomposed into explicitly labeled constituent elements. A valid model may consist of various user-defined elements, for example, substances, products and modifiers involved in processes, or compartments where they are located. Models are not cast directly into a specific form such as differential equations. Many SBML models represent biochemical reaction networks by reactants, called *species* in SBML, that participate in *reactions*, as a substrate, a product, or a modifier (e.g., a *catalyst* of an enzyme catalyzed reaction or an *inhibitor* or *activator*) and that are part of a *compartment*, for example, a cellular substructure or a defined cell. Mathematical descriptions of the reactions within the model, such as the kinetic rate equations or kinetic constants,

are formed using *functions*, *units*, *parameters*, *assignments*, and *kinetic definitions*. The mathematical system can be enhanced using *constraints*, *rules*, and *events*, which can mimic biological phenomena such as feed-source constraints, fixed substrate ratios if needed (e.g., ATP, ADP, AMP balances), nutrient pulse experiments, and more. Every major element carries an identifier, and MathML (see “Relevant Websites section”) is used to encode mathematical descriptions of reactions.

In 2010 the SBML community developed an annotation scheme (Hucka *et al.*, 2015a; Hucka *et al.*, 2018) based on the Resource Description Format (RDF (Lassila and Swick, 1999)) of the guideline standard “Minimum information requested in the annotation of biochemical models” (MIRIAM (Le Novère *et al.*, 2005)) and also based on unambiguous identifiers retrieved from the corresponding registry (Juty *et al.*, 2012). This annotation framework enables users to describe their models, and include standard identifiers, so that models are more reusable and exchangeable. SBML is supported by hundreds of different software tools for reading, writing, simulating, editing, and otherwise working with models encoded in the standard, as well as by many databases and other resources (see “Relevant Websites section”).

CellML

CellML (Cuellar *et al.*, 2003) is a description language to define models of cellular and subcellular processes. At its core, CellML defines lightweight XML constructs that group mathematical relationships within modules. The variables used in mathematics are defined within each module and connections between variables in different modules can be specified. It began development in 1998, completely independently of SBML, in order to support the construction and exchange of cardiac cell models. The first stable specification for CellML 1.0 was released in 2001, at the time of writing the current stable version is CellML 1.1 (Cuellar *et al.*, 2003), but a public draft version 2.0 has been available since May 2017.

Primarily used for describing systems of differential algebraic equations, CellML provides the syntactic constructs to describe mathematical equations in a modular framework called components. One of the key defining features of CellML is its ability to support component-based modeling, allowing models to import other models, or subparts of models, therefore strongly encouraging their reuse (Lloyd *et al.*, 2004; Wimalaratne *et al.*, 2009a) and facilitating a modularized modeling approach. A CellML model typically consists of components, which may contain variables and mathematics that describe the behavior of that component. CellML provides means to reuse and group components into hierarchical structures. Similar to SBML, all entities (elements) carry an identifier and mathematical definitions are encoded using MathML. The mathematical model is considered to be the primary data and biological context is provided by annotating the variables and equations with metadata using Resource Description Format (RDF (Lassila and Swick, 1999)). All numerical values and variables used in a CellML document are required to unambiguously define their physical units that can be defined document-wide, or specifically for certain components. Due to the requirement for physical units, numerical quantities can vary between modules and software is expected to convert units automatically. A CellML metadata standard allows for biological and biophysical annotation of the models (Beard *et al.*, 2009; Wimalaratne *et al.*, 2009b). A wide range of software supports CellML (Garny *et al.*, 2008; Wimalaratne *et al.*, 2009a) and includes software for modeling, visualization, simulation, validation, and conversion. All the software tools can be viewed on the CellML website (see “Relevant Websites section”).

Both CellML and SBML facilitate semantic annotations (e.g., links to controlled vocabularies and ontologies), which further describe the biological meaning of single certain elements (Courtot *et al.*, 2011). Controlled vocabularies and ontologies are detailed later in this article. Neither CellML nor SBML encode what is done with a model nor the results of doing something with it (e.g., simulating it) – these are aspects addressed by other standards such as SED-ML (see below).

Standard for Visualizing Models: The Systems Biology Graphical Notation

When it comes to visualizing networks, each researcher has their own ideas of how the different biological components should be illustrated. The style of diagram can be affected by many factors, including the researchers’ backgrounds, and what elements of the diagram they want to emphasize for their work. This creates bias, and makes creating useful visuals challenging; particularly because each researcher also interprets these figures differently (Kitano *et al.*, 2005). In the same way that electronic circuit diagrams have been standardized in electrical engineering for many decades, consistency and uniformity can be brought to the graphical expression of network diagrams in biology by defining common standards for visualization. The Systems Biology Graphical Notation (SBGN (Le Novère *et al.*, 2009)) standardizes the visual notation used to depict biological networks and processes. The use of such a standard visual notation is vital to ensure that diagrams are unambiguous and consistent. SBGN was first developed in 2006, and is comprised of three languages, which allow biological networks to be viewed from different perspectives and at different levels of detail:

- (1) The process description (PD) variant visualizes biochemical interactions as processes over time (Moodie *et al.*, 2015). As the process map extends from left to right, time evolves, allowing the exact order of reactions to be represented. It is normal in this diagram for the same entity to appear multiple times. PD can describe each process in a network in great detail (e.g., biochemical reaction, binding/unbinding of proteins, and the like) and is useful to represent chemical kinetics models. However, some biological phenomena entail a combinatorial explosion of possible interrelated states, making them extremely difficult to depict at this level of detail (Fig. 1).

Fig. 1 Example of a SBGN process description map. provided by Nicolas Le Novère, UK.

Fig. 2 Example of a SBGN entity relationship map. provided by Nicolas Le Novère, UK.

Fig. 3 Example of a SBGN activity flow map. provided by Nicolas Le Novère, UK.

- (2) The entity relationship (ER) variant visualizes all interactions and relationships between entities, for a given entity (Sorokin *et al.*, 2015). Thereby ER abstracts away the notion of time and focuses on depicting only the relationships between elements, independent of each other. It is useful to represent rule-based models, among other things (Fig. 2).
- (3) The activity flow (AF) variant visualizes the flow of information between biological entities (Mi *et al.*, 2015). So, AF maps focus on the influences between elements rather than the actual processes and are especially useful for representing qualitative models (Fig. 3).

In each instance, a standardized set of entities, and relations visualize the model in a so-called map. A standardized markup language (SBGN-ML) can be used to independently encode the map (van Iersel *et al.*, 2012). SBGN can be used to visualize data and models in SBML and CellML formats, among others.

Standard for Recording Simulation Environments and Setups: The Simulation Experiment Description Markup Language

Consistent and standardized descriptions and formatting of models are not the only requirements for improved reproducible modeling results. Published models are often validated using a set of simulations, and results published from the model are the outcome of a set of virtual experiments. The number of options available to simulate models in different ways, however, can range from diverse algorithms that can run, for example, time courses, steady-states, metabolic control analysis, parameter sensitivities and others, to fixing of various cellular concentrations as precondition, or introducing stepwise changes of variables at specific time-points. This information about a simulation setup can be captured in a method description, but mistakes can be made in recording what steps were taken, and in reimplementing the steps. The Simulation Experiment Description Markup Language (SED-ML (Waltemath *et al.*, 2011b)) was designed to record such descriptive information necessary to rerun a model, such that it can be exported from one simulation tool, and imported into another. These standardized descriptions ensure that virtual experiments, when applied to a computational model, reproduce a given result. So, SED-ML allows the exact simulation setup to be configured and rerun. The first official version was released in 2011. Similarly to SBML, SED-ML evolves in Levels and Versions. The standard is not specific to any simulation software, or modeling format. It is widely used to exchange simulation experiments in computational biology (Olivier and Bergmann, 2015).

SED-ML files record information related to the checklist that describes the minimum information required to understand and reproduce a simulation study, MIASE (Minimum Information About a Simulation Experiment (Waltemath *et al.*, 2011a)). This typically consists of five major blocks of information (Waltemath *et al.*, 2011a; Bergmann *et al.*, 2015):

- (1) Reference to the models being used in the simulation;
- (2) Descriptions of modifications applied to the model before simulation (e.g., the initialization of the variables);
- (3) Descriptions of the simulation steps, including the configuration of the software tool or numerical algorithm;
- (4) Descriptions of the post-processing of result data after simulation; and
- (5) Specifications of the results, including definition of plots and numerical reports.

Libraries to read and write SED-ML are provided by the community and some software tools already consume and export SED-ML files (see “Relevant Websites section”), for example, COPASI (Hoops *et al.*, 2006) or JWS Online (Olivier and Snoep, 2004; Snoep and Olivier, 2003), or Tellurium (Choi *et al.*, 2016). SED-ML elements can also be linked to semantic annotations (Courtot *et al.*, 2011). Simulation Experiment Description Markup Language files can be linked to model descriptions in other formats, notably SBML or CellML, to ensure reproducibility of experiments presented in scientific publications. Such links can, for example, be instantiated via the provision of files in a COMBINE archive (Bergmann *et al.*, 2014), or through provision via public model repositories such as BioModels Database (Li *et al.*, 2010) or the Physiome Repository (Yu *et al.*, 2011).

Recording Modeling Results in a Standardized Way

Similarly to models and simulation setups, communicating the results for *in silico* modeling experiments for exchange, validation, and reuse can be difficult. Results of modeling in the life sciences typically include numerical values, which may also be turned into figures. Numerical results are usually tables or matrices, encoded in CSV (comma-separated values) (Shafranovich, 2005). The flexibility of CSV files means that software and tooling that produces the data can structure and format the data in many different orientations. However, the same data are often structured and labeled differently by each software. This variation hampers ease of exchange, validation, and reuse. Early, generic approaches to providing structure and schema definitions to CSV-like files includes fielded text (Klink, 2016), which is XML-based annotations that describe the header fields of a CSV file. Whilst useful, the amount of life science-specific information that can be used to describe the data is limited. To improve the level of annotation, and to ensure consistent formatting of results data, the Systems Biology Results Mark-up Language (SBRML (Dada *et al.*, 2010)) was developed in 2010. It is specialized for encoding simulation results obtained by running an SBML model. Semantic annotations can be included, with SBRML able to include terms from any ontology that may be relevant to the results. Developing software to analyze the results is also improved by the consistent data structure that can be expected, improving validation and reuse of the data. SBRML is currently being used as a basis to develop a more general results exchanging format NuML (Numerical Markup Language) (see “Relevant Websites section”). The associated library libNUML provides software support for reading, writing, and manipulating data in NuML format on all operating systems (see “Relevant Websites section”).

Metadata, Controlled Vocabularies, and Ontologies for Adding Semantic Information

Sustainable model reuse requires a basic understanding of (1) the biological background, (2) the modeled system, and (3) possible parameterizations under different conditions (Scharm and Waltemath, 2016). This knowledge can be transferred to end-users and computers by using metadata in the form of semantic annotations. Metadata is data about data – it clarifies the intended semantics of the biological data, improving understanding of their scope and validity. Through this it improves the shareability and interoperability of the model (Gennari *et al.*, 2011) – especially computationally. Machine-readable annotations can automate exchange, validation, reuse, composition of models and to convert machine-readable code into human-readable formats (Finney *et al.*, 2006; Misirli *et al.*, 2016; Swainston and Mendes, 2009; Rodriguez *et al.*, 2016). The semantic layer can also be exploited to convert machine-readable code into human-readable formats, such as PDF documents (Dräger *et al.*, 2009; Shen *et al.*, 2010) or visualizations (Junker *et al.*, 2012; Shen *et al.*, 2010) to aid human comprehension.

The metadata can comprise of many things, from free text descriptions, through to inclusion of more formal representations of knowledge like controlled vocabularies and ontologies (Rosse and Mejino, 2003; Bard and Rhee, 2004). Controlled vocabularies are an organized arrangement of precise terms and definitions for a given research domain. They work similarly to a taxonomy system or hierarchical classifications, defining given objects by *is_a* relationships e.g., ethanol *is_a* primary alcohol. Ontologies are similar to controlled vocabularies, but define more comprehensive relationships between objects (e.g., *part_of*, *has_role*). Along with other descriptions, these comprise the information that would be used to semantically annotate data and models, promoting their reuse (Misirli *et al.*, 2016). Terms from controlled vocabularies and ontologies are linked to the entities of a project using semantic technologies, such as the Resource Description Framework (see “Relevant Websites section”) (Lassila and Swick, 1999). There is software available for embedding semantic annotations within spreadsheets, improving semantic adoption among laboratory scientists (Wolstencroft *et al.*, 2011; Maguire *et al.*, 2013).

Especially important ontologies in the domain of modeling in systems biology are (see “Relevant Websites section”):

- Systems Biology Ontology (SBO) (Courtot *et al.*, 2011) designed for models in the domain of systems biology,
- Kinetic Simulation Algorithm Ontology (KiSAO) (Courtot *et al.*, 2011) designed for specifying simulation algorithms and their parameterizations,

- Terminology for the Description of DYnamics (TEDDY) (Courtot *et al.*, 2011) designed for dynamical behaviors and results,
- Just Enough Results Model (JERM) (Wolstencroft *et al.*, 2013) designed to be a minimal descriptor of key information required for ensuring reproducibility of systems biology experiments.

There are also a number of other ontologies and controlled vocabularies that are commonly used within computational systems biology for describing the content and environmental context of models. These include for example, the Gene Ontology (Ashburner *et al.*, 2000), which provides information on genes and their molecular function; the NCBI Taxonomy (Federhen, 2012), which provides information about the nomenclature of organisms; the Protein Ontology (Natale *et al.*, 2014), which provides information about proteins; ChEBI (Degtyarenko *et al.*, 2008), which provides information about chemical compounds of biological interest. In addition, using the vCard ontology (Iannella and McKinney, 2014) it is possible to relate to people and organizations. Using the COMODI ontology it is also possible to encode knowledge about differences between computational models and versions thereof (Scharm *et al.*, 2016).

There are a number of guidelines and checklists available in order to support researchers in annotating their scientific results. For example, the initiative “Minimum Information for Biological and Biomedical Investigations” (MIBBI (Taylor *et al.*, 2008)) provides a general checklist for results in the domain of the life sciences. More specifically, the guideline on “Minimum information requested in the annotation of biochemical models” (MIRIAM (Le Novère *et al.*, 2005)) provides a checklist specifically entailed for computational models. According to MIRIAM, the description of a computational model requires:

- A valid implementation in an appropriate language,
- An initial parameterization,
- Proper metadata about the model provenance (creators, contributors, and creation and modification dates, terms of distribution, etc.) and references to corresponding publications or similar documentations,
- The reproducibility of the references publication/documentation.

Similarly, the guideline on “Minimum Information About a Simulation Experiment” (MIASE, (Waltemath *et al.*, 2011a)) provides a checklist for simulation descriptions of modeling projects. According to MIASE, a simulation experiment needs to specify:

- A comprehensive model including equations and parameterizations,
- A simulation description including precise description of the simulation steps,
- Anything that is necessary to obtain described results.

Survey and Synopsis of Modeling Formats: The NormSys Registry

We have seen that in systems biology, the consistent structuring and description of data and computer models with their underlying experimental or modeling processes is only possible by applying interoperable standards for formatting and describing data, workflows, and models, as well as the metadata describing the interconnection between all these. However, with hundreds of available standards in the field, it is cumbersome for the modelers as potential users of these standards to get an overview about the available formats and supporting standards, as well as their potential fields of application.

To survey some of the most common freely available standards for model description and exchange used in systems biology and related fields, the NormSys registry (see “Relevant Websites section”) was first released in October 2015. This publicly accessible platform provides a single access point for consistent information about these model-exchange formats and aims at listing them in a synopsis to bundle detailed and coherent information about their major features, as well as their similarities, relationships, and differences. The standards are classified by potential fields of application to provide the users guidance on the application of certain standards for a given task (e.g., a certain modeling approach that needs to be implemented) and representative use-cases give concrete model examples for these tasks (Fig. 4). Moreover, possible translation options from one standard to the other are illustrated, as well as interfacing options between the analyzed modeling standards. The standards covered by the first release of the NormSys registry include:

- SBML (Systems Biology Markup Language) as standardized interchange format for computer models of biological processes;
- SBGN (Systems Biology Graphical Notation) as standard for the graphical description of biological networks and pathways;
- CellML as standard for the exchange of mathematical models in biology and physiology;
- FieldML as declarative standard language for building hierarchical models represented by generalized mathematical fields;
- SED-ML (Simulation Experiment Description Markup Language) as standardized format for encoding simulation setups, to ensure exchangeability and reproducibility of simulation experiments;
- SBOL (Synthetic Biology Open Language) to represent genetic designs through a standardized vocabulary and standardized formats;
- NeuroML as a standardized description language that provides a common data format for defining and exchanging descriptions of neuronal cell and network models; and
- PharmML (Pharmacometrics Markup Language) as exchange format for encoding of models, associated tasks, and their annotation in pharmacometrics.

The NormSys registry also comprises an extension for validation and certification of computer models of biological systems that are described in the standard formats. This NormSys model validator, which was released at the end of 2016, includes both a formal syntax

check (XML-based) and a semantic check of the models and the integrity and consistency of their content, their entities, and their annotations. For syntax validation, a generic framework was implemented that makes use of the XML schema information on the corresponding standards stored in the NormSys registry. The consistency and validity of model entities and their corresponding annotations are checked for semantic validation. This semantic annotation test of an uploaded model is performed by a compliance check according to the MIRIAM guidelines (Le Novère *et al.*, 2005), which provide a checklist catalog for model annotations in biology ("Minimum information requested in the annotation of biochemical models").

Computational Lipidomics

Josch K Pauling, Humboldt University of Berlin, Berlin, Germany

Introduction

Lipidomics, the study of the lipidome, is a rather new member of the omics family (Wenk, 2005; Dennis, 2009). A first European initiative with a focus on lipidomics started in 2005/2006 (van Meer *et al.*, 2007). The term *cellular lipidome* refers to the full lipid complement of a cell (van Meer, 2005). It first appeared in a publication by Han and Gross (2003) where the authors describe a mass spectrometry-based method to detect and quantify all lipids in a cell extract, the lipidome. Even though lipids had been known and measured for over three centuries, the ability to now measure the entire lipidome was a great advancement from traditional approaches that focused on efficiently extracting and measuring a single targeted lipid class or species (Hsu and Turk, 2000a,b, 2002, 2003, 2008; Liebisch *et al.*, 2006; Deems *et al.*, 2007; Krank *et al.*, 2007) often in a specific biochemical or biomedical context. Lipids display a great diversity in chemical structure and have distinct chemical properties (van Meer, 2005) and thus measuring lipidomes is a complex task that requires suitable extraction protocols (Folch *et al.*, 1957; Bligh and Dyer, 1959), ionization (Fenn *et al.*, 1989; Ho *et al.*, 2003), detection and quantification techniques (Sandhoff *et al.*, 1999; Ivanova *et al.*, 2007; Almeida *et al.*, 2015), algorithms to automatically read and process mass spectra (Niemelä *et al.*, 2009; Husen *et al.*, 2013; Herzog *et al.*, 2013; Marella *et al.*, 2015; Kochen *et al.*, 2016; Peng and Ahrends, 2016) (explained throughout this article), nomenclature rules (IUPAC-IUB (CBN), 1967, 1977; IUPAC-IUB (JCBN), 1987, 1989a,b; Moss, 1996; Liebisch *et al.*, 2013), databases to store information (Fahy *et al.*, 2005, 2007, 2009; Wishart *et al.*, 2007; Sud *et al.*, 2007; Schmelzer *et al.*, 2007; Foster *et al.*, 2013; Aimo *et al.*, 2015), and software to link and mine this information (Hadadi *et al.*, 2014). Hence, lipidomics research integrates a wide range of scientific disciplines such as biochemistry, mass spectrometry, bioinformatics, computational biology, biomedicine and biophysics.

Lipids and Functions

Cellular lipids are biomolecules with a very high structural and functional diversity (Gross and Han, 2011). Glycerophospholipids, for example, consist of a hydrophilic head group and two hydrophobic hydrocarbon tails. Together with sphingolipids and cholesterol they can create lipid bilayers (Edidin, 2003; van Meer *et al.*, 2008) that separate two aqueous environments from each other. Within a cell these lipid bilayers act as biological membranes creating cellular compartments. A membrane is the site of metabolic exchange between the organelle and the extra-organelle environment, for example, the cytosol with membrane proteins managing the actual exchange and transport across the membrane. The composition of lipids determines the specific membrane properties such as structure and fluidity. The regulation of membrane-lipid composition is very rigid and slight alterations in it can impair membrane functionality.

Another, and widely known, function of lipids is the storage and provision of cellular energy. Glycerolipids, especially triacylglycerols (TAGs), are storage lipids that serve as carriers of fatty-acids. They consist of a glycerol backbone where fatty-acyl side chains are attached. A TAG consists of three fatty-acyl side chains, which is the maximal number that can be directly attached to a glycerol. Through enzymatic activity these fatty-acyl side chains can be released from the glycerol providing non-esterified fatty-acids (NEFAs), which can serve as a source of ATP when oxidized. There are many more lipids and functions but glycerophospholipids, specifically phosphatidylcholine (PC 34:1 as shown in Fig. 1) will be used in following examples.

Computational Lipidomics

The lipidomics workflow starts with extracting lipids from a cell or tissue sample. Protocols such as the one proposed by Folch *et al.* (1957) or by Bligh and Dyer (1959) have been widely used for decades and the corresponding publications have received

Fig. 1 Chemical structure of a phosphatidylcholine (PC). Together, both fatty-acyls consist of 34 carbon atoms and one double bond (PC 34:1). A shorthand notation of this particular species is PC 16:0/18:1 indicating the position-specific distribution of fatty-acyls. A fatty-acyl with 16 carbon atoms is bound to the stereospecific numbering (sn)-1 position of the glycerol. A fatty-acyl with 18 carbon atoms and one double bond is bound to the sn-2 position of the glycerol. Given that the depicted double bond is of the *cis*-type (Z according to the E-Z-scheme) the full name is 1-hexadecanoyl-2-(9Z-octadecenoyl)-sn-glycero-3-phosphocholine according to IUPAC nomenclature rules.

Fig. 2 The lipidomics workflow from a sample to an interpretation in the context of integrated omics analyses. This scheme is described in this article.

over 50,000 and over 40,000 citations, respectively. After extraction, a feasible mix of exogenous lipid standards is selected and added to the extract (Moore *et al.*, 2007). Finally, the sample extract is injected into a mass spectrometer for measurement. There are various mass spectrometric methods but the basic decision is whether or not to apply a chromatographic separation prior to injection, for example, liquid chromatography (LC/MS) or gas chromatography (GC/MS) (McDonald *et al.*, 2007; Sullards *et al.*, 2007; Cruz-Hernandez and Destailats, 2012). The alternative is to inject the sample extract directly into the electrospray ionization (ESI) device of a mass spectrometer. This is called “shotgun lipidomics” (Han, 2003; Han and Gross, 2005; Schwudke *et al.*, 2007, 2011; Schuhmann *et al.*, 2011, 2012).

The path from generating a set of mass spectra to algorithms mining this data and meta data by querying multiple databases is a very long and tedious one (Fig. 2). The first few steps are very technical and require detailed background knowledge of lipid biochemistry and mass spectrometry. Mass spectra representing a lipidome are generated and a readout is stored. Subsequently, the data must be analyzed and prepared in a way that meta data is quickly accessible. This includes quality control mechanisms and statistical analysis. At last there are classical bioinformatics tasks such as database development, data mining and linking the data to other omics data sets, for example, to study health and disease. At this point, the applied bioinformatics methods are not specifically tailored to deal with lipidome data and may therefore be more generally summarized as “lipid bioinformatics”. However, the earlier steps are highly specific to mass spectra of lipidomes and may thus rather be termed “computational lipidomics” which is in the focus of this article.

Mass Spectral Analysis and Peak Detection

High throughput, high resolution lipid experiments may become quite complex when measuring various different tissue samples under various conditions at different time points with biological and technical replicates. This may result in thousands of mass spectra contained in a single data set. Experts can analyze a mass spectrum quickly by looking at it but this method is not feasible for more than about one hundred mass spectra. Automated routines are necessary to analyze such a data set in an adequate time frame. The first step in such a routine is to identify peaks that each resemble lipid molecules of a specific mass per charge ratio (m/z) in a long list of data points which comprise two values (1) m/z value and (2) intensity. Ideally, these data point lists, typically one list per mass spectrum, are kept in computer memory. However, mass spectrometer vendors keep the format in which mass spectra are stored secret and instead provide software tools to convert them to regular tab- or comma-separated text files. Reading and storing the lists in memory is followed by a peak detection heuristic that maps groups of data points to one peak and determines this peak’s centroid m/z and intensity tuple. It is important to note that this is not always a straight forward process as

Fig. 3 Various schemata of peak appearances in a mass spectrum. (a) through (c) may depict two or more convoluted peaks. The higher the resolution of the mass spectrometer the more molecules are fully resolved as singular peaks.

shown in Fig. 3. In most of the depicted peak schemata the peak is not resembling a clean Gaussian distribution of intensities over the peak width and in some cases one may observe multiple peaks that could not be fully resolved. The challenge is to deconvolute overlapping peaks and to estimate the m/z and intensity values for each peak. The apex value of a fitted Gaussian bell curve is a good estimator to start with but more sophisticated solutions are needed when this method fails.

Identification and Quantification of Lipids

Assuming that m/z values and intensities have been assigned to each peak, the m/z value can be utilized to annotate each peak with the name of the lipid it resembles. This identification process is vastly dependent on the accuracy of the assigned m/z value and the calibration of the mass spectrometer at the time of measurement. A shift in m/z values may result in a false mapping to a lipid with a slightly higher or lower m/z value. It is therefore essential in quality control to become aware of and correct for such shifts that may occur over the time of a measurement and can only be detected by measuring control samples in between the actual samples. Additionally, there exist lipids with the same atomic composition but yet different chemical structure. These are isomeric molecules and it is not possible to distinguish one from the other just by the peak m/z value.

After mapping every peak to a lipid species the intensity value is utilized to quantify the full complement of lipids in the sample of interest. Normalization is key to guarantee comparability between several mass spectra and experiments. Prior to injection into the mass spectrometer, a mix of internal standards (non-endogenous lipid species) of specific and exact amounts is added to each sample extract to obtain a relationship between the peak signal and the actual concentration in the sample. Lipid class intensities can then be normalized to the respective lipid standard. Doing so ensures that intensity values from different mass spectra become directly comparable. At the same time, differences in ionization efficiencies between lipid classes are corrected.

In a final step after normalization all detected and identified lipids including their intensities are reassembled to formulate the lipidome of a particular sample. To acquire a complete data set, this procedure is done for each sample measured as a part of an experiment. In case one fills an entire 96-well plate with samples, controls, and blanks this is an enormous effort that requires sophisticated computational support.

The Next Dimension

The previous section provided insights into the computational challenges to solve when measuring a lipidome based on intact lipid molecules (abbreviated as MS or MS1). This measurement is not sufficient to reveal the particular fatty-acyl side chains on one of those lipid species or to resolve isomeric lipids. All one can infer from the m/z value is the atomic composition of the whole molecule but not its structural arrangement. In lipid research it is often of interest to track fatty-acid metabolism and the side chains of membrane glycerophospholipids. To achieve this information it is necessary to break a lipid into smaller fragments, for example, via collision-induced dissociation (CID) (Sleno and Volmer, 2004; Wells and McLuckey, 2005). With this technique (abbreviated as MS2, one fragmentation step) it is possible to dissociate the fatty-acyl side chains and the head group from the glycerol backbone and afterwards measure the m/z values of these fragments. This allows to infer the particular fatty-acyls. Fig. 4 guides through this process. Finally, fragments may be fragmented again to reveal even further structural detail (abbreviated MS3, MS4, etc., or simply MS n , where n denotes the number of fragmentation steps).

The lipid molecule of interest, a PC 34:1, has a m/z value of 760.58 Da. Multiple peaks are shown each representing fragments with lower m/z values. The dissociated part of the molecule did not have a charge and is therefore not represented in the mass spectrum. This is called a neutral loss (NL) while the observable charged fragment is called a product ion. The neutral loss can occur in two slightly different ways leaving the two peaks at 478 and 496 Da. The corresponding compounds are shown above. However, according to the mass difference between the complete lipid molecule and the fragments one can infer that in both cases a fatty-acyl with 18 carbon atoms and one double bond is the missing part of the fragment. Hence, the presence of the sub-species PC 16:0–18:1 can be confirmed. The same procedure can be applied to all peaks in the mass spectrum. Doing so additionally shows the neutral losses of different fatty-acyls (red annotation) revealing the presence of another sub-species PC 16:1–18:0 in which the double bond is found on the shorter fatty-acyl. Fragmentation by collisional dissociation is a powerful tool to detect lipid molecules with a high level of structural detail. However, it too has its limitations since some structural details such as double bond type and position and the position of hydroxyl group modifications cannot directly be detected.

Fig. 4 A raw mass spectrum of fragmented PC 34:1 as it is generated by a mass spectrometer. The spectrum in front depicts a zoom in the m/z range between 440 and 540 Da as indicated by the horizontal, orange lines. The spectrum in the back shows the entire mass range and the prominent peak at 184, a phosphocholine. The chemical structure of this fragment is shown above. The other peaks strongly suggest that there are two detected sub-species (labels in black and red). The corresponding fragments to each peak are shown above. From the evidence one can deduce that there is not only the black labelled molecule PC 16:0–18:1 but also the red labelled PC 16:1–18:0. These are molecules with different chemical structure but with the same atomic composition and m/z value. For simplicity, the structure of the red labelled PC 16:1–18:0 is not shown. On top of the figure only the black labelled PC 16:0–18:1 is shown. Please also note that the sn-position of the fatty-acyl side chains cannot be deduced from a peak's m/z value. Therefore, the annotation "PC 16:0–18:1" is used instead of the position-specific annotation "PC 16:0/18:1" despite the position-specific graphical structure of a PC 16:0/18:1.

When fragmentation is utilized in an experiment the number of mass spectra is significantly increased from hundreds (one mass spectrum per well on a 96-well plate, double injections) to possibly several thousand. The challenge is to automate the process described in Fig. 4 and to accurately infer the various fatty-acyl side chain compositions for a particular lipid species. Fig. 5 depicts the difference between a MS measurement and a MS2 (or MSn) measurement visualized as a schematic bar plot.

With the progression and advancement of today's analytical capacities from smaller scale lipid studies to large scale high-throughput scans of full lipidomes and from whole molecule identification to a higher degree of structural detail it will continue to be a vital task to co-develop computational support routines. To develop sophisticated solutions it is essential to further expand on interdisciplinary expertise in the lipid-oriented research community. In comparison with other omics technology the range of lipid-centric informatics solutions is currently small and it is therefore not surprising that the few existing ones may not be usable free of charge. It is advisable to acquire a solid basic understanding of how computational biology support has helped to fuel the advancement of the omics landscape. Lipidomics and proteomics are largely mass spectrometry-based disciplines. Thus, computational lipidomics can profit from translational efforts. This, however, requires at least basic expertise in proteomics, lipidomics, and computational biology as well as bioinformatics and potentially additional disciplines. In today's biomedical research, there is already a need for position-specific structural characterization of lipid molecules on a lipidome-wide scale within a multi-omics setting. This underlines the importance of the emerging field of computational lipidomics research.

Fig. 5 The levels of detail gained from either a full MS scan or a MS2 up to MS_n fragmentation analysis. The stacked bar on the right visualizes the sub-species composition. The exact quantity of detected sub-species cannot accurately be determined solely based on fragment spectra and must be approximated.

Multi-Scale Modelling in Biology

Socrates Dokos, University of New South Wales, Sydney, NSW, Australia

Introduction

Multi-scale modelling aims at developing computational models of physical systems characterised by phenomena spanning multiple spatial or temporal scales. Non-biological examples include modelling whole-material properties from microstructural and molecular-level features (Horstemeyer, 2009), chemical engineering processes from molecular-level interactions (Saliccioli *et al.*, 2011; Zhao *et al.*, 2012), nuclear reactor design (Mahadevan *et al.*, 2014) and astrophysics (van Elteren *et al.*, 2014). In biology and physiology, multi-scale models are often used to integrate biological processes operating from the molecular and sub-cellular scale through to cell and tissue function, up to whole-organ and organ systems (Hunter and Nielsen, 2005; Southern *et al.*, 2008; Qu *et al.*, 2011). Examples include biomechanics (Viceconti, 2012), electrophysiology (Winslow *et al.*, 2000), pulmonary gas exchange (Donovan, 2011), tissue patterning (Thorne *et al.*, 2007), tumour growth (Zangooei and Habibi, 2017), biochemical signalling pathways (Walker *et al.*, 2008) and systems biology in general (Dada and Mendes, 2011). An overview of the typical spatial scales employed in multi-scale biological models is shown in Fig. 1.

Multi-Scale Modelling Approaches

Approaches to formulating multi-scale models and their computational implementation will depend on the choice of spatial scales adopted, as well as the particular physics being coupled.

Model Formulation

Multi-scale models are generally constructed from one or more sub-component models, each characterised by a finer spatial and/or temporal scale than the overall model. Integration of these into a single coarse scale model involves some degree of macroscopic approximation, loosely termed *homogenisation* (across space) or *averaging* (across time) (Matthies, 2006). These methods include model reduction and course-graining (Gorban *et al.*, 2006), continuous field approximation (Bonilla *et al.*, 2014), compartmental and lumped-parameter modelling (Quarteroni *et al.*, 2016) and cellular automata approaches (Ermentrout and Edelstein-Keshet, 1993).

Fig. 1 Typical biological spatial scales used in multiple-scale modelling. Larger scales are shown typical for human physiology.

Course-graining methods approximate spatial heterogeneities by discretising the model's spatial domain into course regions, assigning spatially-averaged properties of the original system to each. In molecular dynamics simulations for example, instead of representing the kinetics of every atom in a system, groups of atoms are clustered together into single mesoscale entities, to provide a simplified, low-resolution approximation (Saunders and Voth, 2013). In contrast, *model reduction* seeks to lower the total degrees of freedom in a system of equations by projecting state variables onto lower-dimensional subspaces whilst preserving overall model behaviour. A simple example is Fitzhugh's (1961) reduction of the Hodgkin and Huxley (1952) equations of neural electrical activity from four state-variables to two, subsequently known as the Fitzhugh-Nagumo model.

In biology, many multi-scale models are typically formulated using *continuous field approximation*, in which reaction-diffusion equations are used to represent macroscopic properties of the system. For example, to model the propagation of electrical activity in excitable tissues such as the heart, the complex network of constituent interconnected cells can be represented using a simplified continuum approximation of cell membrane potential at each point in the tissue (Pullan et al., 2005) (see also section "Modelling Spatial Propagation of Electrical Activation in Heart Tissue" below). Another approach to multi-scale model formulation is the use of *lumped-parameter* or *compartmental* descriptions to represent separable model components such as, for example, modelling of insulin-glucose kinetics using only two discrete intercellular and blood plasma compartments (Tolić et al., 2000). Finally, *cellular-automata* models have also been used to represent multi-scale biological systems, in which simplified rule-based descriptions are employed to characterise biological function of constituent unit components. An example is the cardiac arrhythmia model of Mitchell et al. (1992), who used cellular automata to characterise single-cell electrical activity, modelling electrical conduction at the whole-tissue level.

Computational Implementation

To solve multi-scale biological models, commercial multiphysics finite-element numerical software such as COMSOL Multiphysics (COMSOL AB, Switzerland) (Dokos, 2017), or SIMULIA (Dassault Systèmes Simulia, USA) (Baillargeon et al., 2014), are increasingly being employed, along with a range of specialised open-source software platforms including OpenCMISS (see "Relevant Websites section"), Chaste (see "Relevant Websites section"), CHeart (see "Relevant Websites section") and Continuity (see "Relevant Websites section"): the latter platforms utilised within multi-scale biological modelling frameworks such as the Physiome Project (see "Relevant Websites section") (Hunter et al., 2008). Increasingly important to multi-scale biological model development are mark-up language specifications for biological/physiological systems including SBML (see "Relevant Websites section"), CellML (see "Relevant Websites section") and FieldML (see "Relevant Websites section"). Similar multi-scale computational frameworks have been described for chemical process engineering applications (Yang, 2013). An advantage of such frameworks is that, at least in principle, models of component subsystems can be readily swapped in and out from existing model libraries, providing a powerful means of formulating multi-scale biological models (Cooling et al., 2010).

Case Study – Modelling Cardiac Function

An interesting example of multi-scale modelling applied to biology is in the area of cardiac electromechanics, whereby ion channel dynamics in individual cardiomyocytes determines the pattern of electrical activation of the whole heart and its associated contractile performance (Land et al., 2012). Such models could have important applications for a range of patient-specific cardiovascular therapies in future, including development of antiarrhythmic drugs for long-QT syndrome (Hunter and Smith, 2016). A multi-scale model of the heart will incorporate a geometric description of the heart and its chambers, coupled to spatially-heterogeneous models of ion channel kinetics, local wall microstructure and active force generation, all linked to a lumped-parameter description of the circulation system acting as a load on the heart, as shown in Fig. 2.

Single-Cell Ionic Models

The basic modelling unit of multi-scale cardiac electromechanics is the single-cell ionic model of cardiac electric activity. Ion flow through voltage-gated transmembrane pores can be experimentally determined from patch-clamp data, yielding whole-cell membrane current macroscopic approximations expressed using either Hodgkin and Huxley (1952) formalism, or as Markov-type models (Hille, 2001). For example, in the human ventricular myocyte model of ten Tusscher et al. (2004), the rapid potassium ionic current I_{Kr} can be expressed in Hodgkin-Huxley form as

$$I_{Kr} = G_{Kr} \sqrt{\frac{[K]_o}{5.4}} x_{r1} x_{r2} (V_m - E_K)$$

where V_m is the membrane potential, G_{Kr} is the maximum membrane conductance of I_{Kr} channels, E_K is the equilibrium potential for potassium, $[K]_o$ is the extracellular potassium ion concentration, and x_{r1} , x_{r2} are gating variables, each governed by a first-order ordinary differential equation of the form

$$\frac{dx_{r1}}{dt} = \alpha_{r1}(1 - x_{r1}) - \beta_{r1}x_{r1}$$

where α_{r1} , β_{r1} are rate coefficients that are empirical functions of the membrane potential V_m . The same ionic current can be expressed also in Markov form, whereby several channel states are defined as either open, closed or inactive, and transition rates

Fig. 2 Multiscale model of cardiac electromechanics, according to Bakir *et al.*, 2017 illustrating multi-physics coupling between cardiac electrical activation (activated regions shown in red, quiescent regions in blue), blood dynamics (shown as velocity streamlines within the left and right ventricular cavities), and lumped-parameter models of systemic and pulmonary circulations. Also shown are the tree-like structures corresponding to the rapidly-conducting cardiac conduction system.

between these states are given as a function of membrane potential V_m (Bett *et al.*, 2011). If the fraction of open states is given by O , then

$$I_{Kr} = G_{Kr} O (V_m - E_K)$$

Summing together all the ion currents present in the cell to form the total ionic current I_{tot} , leads to the space-clamped equation for membrane potential:

$$\frac{dV_m}{dt} = -\frac{I_{tot}}{C_m}$$

where C_m is the membrane capacitance per unit area. This formulation allows for the reconstruction of a cardiac action potential waveform, given an external stimulus of sufficient magnitude (added to I_{tot} in the above).

Several single-cell cardiac ionic models are available from the CellML online repository (see “Relevant Websites section”) (Lloyd *et al.*, 2004), which can be used to specify different expressions for I_{tot} in various regions of the heart. Many of these ionic models also include intracellular compartments for simulating calcium ion transients or other ions, second messengers and metabolites.

Modelling Spatial Propagation of Electrical Activation in Heart Tissue

Once I_{tot} has been specified for each region of the heart, propagation of electrical activation across the myocardium can be simulated using the macroscopic continuum approximation of excitable tissues known as the *monodomain formulation* (Cloherty *et al.*, 2006):

$$\beta \left(C_m \frac{\partial V_m}{\partial t} + i_{ion} \right) = \nabla \cdot (\sigma \nabla V_m)$$

where β is the tissue cell membrane surface-to-volume ratio, σ is the tissue conductivity, and ∇ is the *nabla* or *del* spatial partial derivative operator, given in 3D by

$$\nabla \equiv \begin{pmatrix} \frac{\partial}{\partial x} \\ \frac{\partial}{\partial y} \\ \frac{\partial}{\partial z} \end{pmatrix}$$

If the myocardium is *isotropic*, that is its physical properties are not dependent on spatial orientation of the tissue, then σ will be a scalar. In the general case however, myocardial tissue is anisotropic, both in its electrical and mechanical properties, with electrical conductivity dependent on local fine microstructure of the tissue. This microstructure consists of cardiac muscle *fibres* and *fibre sheets*, representing layers of bundled fibres. An orthogonal set of local coordinate axes can then be defined along the fibre, sheet, and normal-to-sheet directions, with electrical conductivity greatest along the fibre axis, followed by the sheet, then the normal-to-sheet axis (Hooks *et al.*, 2007). Defining the unit vectors of these local fibre, sheet and normal axes with respect to the global coordinate system as $\hat{\mathbf{f}}$, $\hat{\mathbf{s}}$, $\hat{\mathbf{n}}$, we can define the conductivity *tensor* for use with the monodomain equation as

$$\sigma = \sigma_f \hat{\mathbf{f}} \otimes \hat{\mathbf{f}} + \sigma_s \hat{\mathbf{s}} \otimes \hat{\mathbf{s}} + \sigma_n \hat{\mathbf{n}} \otimes \hat{\mathbf{n}}$$

where σ_f , σ_s and σ_n denote the scalar conductivities along the local fibre, sheet and normal-to-sheet orientations respectively, and $\otimes$ denotes the tensor outer product. Note that the orientation of the local microstructural axes will vary with spatial position in the heart.

Modelling Passive and Active Mechanical Properties of the Myocardium

In addition to electrical function, passive mechanical properties of the myocardium will also depend on the local microstructure (Dokos *et al.*, 2002). These properties can be expressed using a continuum mechanics approximation of the tissue, typically though use of a *hyperelastic* constitutive law, such as that of Holzapfel *et al.* (2000):

$$W = \frac{c_0}{2} (\bar{I}_1 - 3) + \frac{c_{f1}}{2c_{f2}} \left[e^{c_{f2}(\bar{I}_f - 1)^2} - 1 \right]$$

where W denotes a scalar *strain energy* function, $\bar{I}_1$ is the first invariant of the Cauchy-Green deformation tensor, c_0 , c_{f1} and c_{f2} are material parameters of the tissue, and $\bar{I}_f$ denotes the stretch along the fibre direction $\hat{\mathbf{f}}$. Detailed step-by-step implementation of this material description for myocardium using COMSOL Multiphysics software is given in Dokos (2017).

Many cardiac single-cell ionic models also contain descriptions of cytosolic calcium transients, which can be used to model calcium ion interaction with contractile proteins to generate active force (Hunter *et al.*, 1998). Other models simply link active force generation to the membrane potential itself (Nash and Panfilov, 2004). Either way, these models can be used to generate active tension T_a , which can then be incorporated into the passive strain energy function to determine the 2nd-Piola Kirchhoff stress tensor components S_{ij} within the myocardium according to

$$S_{ij} = \frac{\partial W}{\partial E_{ij}} + T_a \hat{\mathbf{f}} \otimes \hat{\mathbf{f}} + \gamma T_a \hat{\mathbf{s}} \otimes \hat{\mathbf{s}} + \gamma T_a \hat{\mathbf{n}} \otimes \hat{\mathbf{n}}$$

where E_{ij} are the components of the Green strain tensor, and γ represents the fractional component of active tension in the cross-fibre directions due to fibre branching. Passive constitutive laws coupled with active force generation allows structural deformation of the myocardium to be determined (Holzapfel, 2000).

Modelling Fluid Dynamics and Circulatory Blood Flow

Blood flow within the ventricles can be modelled using incompressible Navier-Stokes equations (Fung, 1997):

$$\rho \left(\frac{\partial \mathbf{u}}{\partial t} + \mathbf{u} \cdot \nabla \mathbf{u} \right) = -\nabla p + \mu \nabla^2 \mathbf{u}$$

$$\nabla \cdot \mathbf{u} = 0$$

where $\mathbf{u}$ is the fluid velocity field and p is its pressure, ρ is the fluid density and μ its viscosity. Boundary conditions for the fluid equations include a moving wall condition on the endocardial surface, whereby the fluid velocity is set to equal the velocity of the moving wall determined from the structural mechanics deformation. Because of the deforming fluid domain, a moving mesh approach must also be implemented, known as the Arbitrary Lagrangian-Eulerian (ALE) method (Donea *et al.*, 2004). In turn, the fluid pressure p can be used as an endocardial boundary load for the wall deformation mechanics. In practice however, the pressure will be nearly-constant across the surface at each time instant. As a result, most multi-scale models of cardiac electromechanics omit the Navier-Stokes equations, determining the endocardial fluid pressure load from the circulatory load model instead.

As shown in Fig. 2, the circulatory load on the heart can also be approximated by hydraulic circuits, analogous to electric circuits where the analogue of current is fluid flow rate, and the analogue of voltage is fluid pressure. Also shown are capacitive elements, representing the compliance of arteries and veins due to their elastic distensibility. These circuit elements are lumped parameter representations of circulatory components including tissue beds, large arteries and the lungs.

Multi-Scale Overview of Cardiac Electromechanics

From the above descriptions, it is evident that the multi-physics model of cardiac electromechanics combines several spatial scales into a single, albeit complex, model formulation. Beginning with the membrane ionic channels, whose properties can be modelled at the molecular level using molecular dynamics, a macroscopic representation of their function is adopted in the form of Hodgkin-Huxley formalism or Markov-state models. These descriptions of membrane currents are then incorporated into single-cell electrophysiology models, which can additionally include expressions for sub-cellular ionic concentrations, metabolites, contractile processes and signalling pathways. The cell models can then be combined into the monodomain macroscopic formulation of tissue electrical activity to solve for the propagating electrical activation wavefront. Similar macroscopic approximations are also made for the passive and active structural mechanics, incorporating features of the local fine tissue microstructure. Finally, the entire circulation, which sets the loading conditions on the heart, is approximated as a lumped-parameter description, representing various components of the vasculature.

Conclusion

Biological systems are inherently complex, characterised by multiple phenomena operating at various spatial and temporal scales from the molecular and sub-cellular, through to whole-cells and tissues, up to the whole-organ level and beyond. Multi-scale modelling approaches are well-suited to the study of biological systems, integrating knowledge of the various subsystems into a coherent understanding of whole-system properties and function. In future, with ever-increasing computational power becoming available, multi-scale models will undoubtedly yield fundamental insights into numerous complex biological phenomena, even playing a key role in drug design and personalised therapies.

Introduction

The extraordinary availability of large sets of data produced in biotechnology through the advancement of information technology is promoting the amplification of the knowledge of biological systems. These innovations have swung the pendulum in the way biomedical research, development and applications are done. Clinical data complement biological data, enabling detailed descriptions of various healthy and diseased states, progression and responses to therapies. The amount of data representing various biological states, processes, and their time dependencies enable the study of biological systems at various levels of organization, from molecule to organism, and even at population levels. Multiple sources of data support a rapidly growing body of biomedical knowledge; however, our ability to analyse and interpret these data lags far behind data generation and storage capacity.

Mathematical and computational models are increasingly used to help interpret biomedical data produced by high-throughput genomics and proteomics projects. Advanced applications of computer models that support the simulation of biological processes are used to generate hypotheses and plan experiments. Appropriately interfaced with biomedical databases, computational models are necessary for rapid access to and sharing of knowledge through data mining and knowledge discovery approaches.

The immune system (IS) represents one of the most fascinating systems from many points of view, including biology, physics, computer science and mathematics. Together with the central nervous system, it is probably the most complex, adaptive and highly distributed system in life sciences. It constitutes the fundamental defence mechanism of the vertebrate animals, including human beings, from invading from the pathogens and harmful foreign substances. Following the evolution of multicellular organisms, the immune system developed various defence mechanisms and abilities against all kinds of pathogens, like viruses, bacteria, fungi and other parasites.

Innate Immune System

The “evolutionary-older” mechanisms belong to the class of “innate immunity” defences, and include physical barriers, soluble mediators that directly inhibit foreign micro-organisms and specialized cells able to phagocytose and kill micro-organisms.

The simplest physical barrier is represented by the skin which gives a very effective protection from infection. The mildly acidic pH of skin also inhibits bacterial proliferation. Moreover, the blood coagulation system stops the bleeding, and creates a protective clot over wounds, while the internal mucosae inhibits foreign invaders from entering in the organism. The very acidic pH of stomach juices is also able of effectively sterilize ingested materials. Even the mechanisms that regulate the host temperature (i.e. fever) represent a defence mechanism against the proliferation of some pathogens.

Many soluble molecules such as defensins (natural antibiotics), lysozyme (an enzyme that lyses the wall of some bacteria), the complement (a system of proteins activated in cascade in the cell membrane of certain pathogens that result in their lysis), opsonins (molecules that coat pathogens and facilitate phagocytosis) and some ancient cytokines such as interferons can inhibit viral infections and also kill bacteria.

Innate immunity is also composed by many cellular-driven mechanisms that include the cellular migration toward invaders and phagocytosis, followed by intracellular destruction of the ingested micro-organism. Extracellular killing is also possible if phagocytes release substances that can cause lysis. In mammals such actions are carried by granulocytes and macrophages. The former contains intracellular granules with lytic substances, whereas the latter emigrate to practically all tissues and organs to carry out their phagocyte functions, also important in the turnover of aging cell components.

Even if their evolution is relatively recent and goes in parallel with the evolution of lymphocytes, natural killer (NK) cells are commonly considered as non-phagocytic innate immunity cells, and are able to kill virus-infected cells.

In innate immunity, the recognition of pathogens is done thanks to the presence of pathogen-associated molecular patterns expressed by micro-organisms. Cells belonging to innate immunity hold receptors, globally referred to as “pattern-recognition receptors”, that are able to recognize and match with such molecular patterns. These receptors include the family of Toll-like receptors (TLR), mannose receptors (MR) and seven-transmembrane spanning receptors (TM7). TLR recognize bacterial and viral nucleic acids, flagellin, bacterial peptides, lipopolysaccharide (LPS) and other bacterial components. MR receptors bind carbohydrate moieties of several pathogens, such as bacteria, fungi, parasites, and viruses. Finally, TM7 receptors are activated by bacterial peptides or by endogenous chemokines.

Adaptive Immune System

The evolutionary process brought to the developing of newer adaptive and specific responses that couple the classical innate (or natural) immune responses. Adaptive immunity is in fact evolutionary recent. Starting from sharks, the evolution of adaptive immunity followed those of vertebrates, contributing to their evolutionary success and their long life spans. It should be said that adaptive immunity must be seen as a complement of innate immunity, as the two systems strongly interact and cooperate to eradicate pathogens.

Lymphocytes represent the principal effectors of adaptive immunity. Lymphocytes circulate in the blood, tissues, lymphatic vessels and reside in lymphoid organs, which include the thymus, the spleen and lymph nodes. Why are lymphocyte functions so different from innate immunity cells? The answer can be reassumed as follows: specificity, memory and immune tolerance. The lymphocyte population is composed by millions of clones specialized (thanks to their clonotypic antigen receptors) in recognizing a specific antigenic sequence. Only the clones that express the receptors capable of recognizing a specific micro-organism are activated and thus proliferate upon infection, while the others remain inactive. A unique random DNA rearrangement procedure is responsible to bring, from a relatively small pool of DNA sequences, billions of different receptors (a theoretical estimate is of the order of 10^{20}). The immunological meaning of memory represent the capability of lymphocytes to “remember”, thanks to specialized memory cells, the first encounter with a given antigen (primary immune response) in order to respond more promptly and more efficiently to subsequent encounters (secondary immune response). Immune tolerance is a selective mechanism used by the immune system to exclude potentially autologous (self) lymphocytes clones through their destruction or their inactivation.

Lymphocytes populations can be distinguished in many ways, starting from the different types of antigen receptors or different specific functions. The most fundamental distinction is between T and B cells. B cells are the main effectors of the so-called “humoral response” and use immunoglobulins(Ig)-like membrane antigen receptors. After recognition and stimulation by the antigen, activated B cells differentiate into plasma cells which secrete a soluble form of the receptor, called antibody. The help of CD4 T-cells (helper T-cells) is a fundamental requirement to mount an appropriate response of B-cells in producing mature antibodies. Each antibody molecule is a dimer of a heavy and a light chain, and each one has a variable and a constant part. The basic antibody molecule is Y-shaped with two independent antigen-binding sites (at the ends of the diagonal segments of the Y). The constant stem of the Y mediates the so-called effector functions of the antibody. We can distinguish among various classes of antibody types. IgM are the first antibodies produced during the primary immune response. IgG are the main class of antibodies released in blood during secondary immune responses. In humans there are four different IgG types (IgG1, IgG2, IgG3 and IgG4). IgA are specialized for functioning in secretions like milk, tears, saliva and intestinal. IgE are best known in conjunction with allergies.

Antibodies bind and inactivate their cognate antigens, and with different mechanisms they promote immunity against foreign pathogens. Antibodies binding to cell membranes may activate the complement system that can lead to cell lysis. Moreover, leukocytes that express surface receptors for the constant stem of antibodies can act with phagocytosis (opsonization) and cell lysis (antibody-dependent cell-mediated cytotoxicity, ADCC) of antibody-bound cells. In this way, macrophages or NK cells acquire the antigen specificity of adaptive immunity. Finally, insoluble antigen-antibody complexes (immunocomplexes) can be rapidly removed from the host.

T cells instead represent the main effectors of the “cell-mediated response”. There are many important differences between B and T cells. First, antibodies are at the same time the receptor and the effector molecule of B cells, while the T cell receptor (TCR) is a membrane receptor that activates a series of effector actions mediated by other molecules. Moreover, antibodies can bind any conceivable molecular species such as proteins, lipids, sugars and small organic molecules while T cells receptors are specialized in recognizing only small peptides on the surface of cells. Furthermore, antibodies recognize the antigen in its free native form, whereas TCRs recognize only specific peptides present on the host cell membrane bound to a cellular protein called Major Histocompatibility Complex (MHC), not the whole antigen structure.

There are various T cell populations. Cytotoxic T cells (Tc, also referred to as CTL) directly kill cells expressing the antigen, helper T cells (Th) promote the activities of B and Tc cells, while regulatory T cells (Treg) modulate the immune responses. The Th population can be further distinguished in Th1 and Th2 sub-populations, according to the cytokines they secrete. The former mostly release gamma-interferon and other cytokines to stimulate immune responses against virus and intracellular bacteria, whereas the latter release interleukin 4 (IL-4) against parasites.

Adaptive immune response involves a complex cooperation between both innate and adaptive cells. In general, immune responses start on the periphery of the body where antigen presenting cells (i.e., cells that commonly are able to process and endocytose antigenic sequences or proteins) capture an antigen and move through lymphatic system towards lymph nodes. Here they present the antigenic peptides exposed on their membrane in conjunction with MHC molecules to Th cells and secrete interleukins, such as Interleukin 12 (IL-12), to promote Th responses. Th cells with specialized TCR for the target antigen are activated by both recognition and co-stimulatory molecules.

Activated Th cells proliferate and secrete other cytokines activating antibody production by B cells and replication of Tc cells. Antibodies, Th and Tc cells reach the periphery where they encounter the pathogen. Antibodies bind to pathogens promoting, for example, phagocytosis by macrophages, activation of the complement system and the ADCC in conjunction with NK cells, respectively. Th cells secrete multiple cytokines with diverse functions such as attraction of other leukocytes in the place of infection, inhibition of viral replication and stimulation of haemathopoiesis to increase the number of leukocytes. Tc cells recognize and directly kill infected cells expressing peptide-MHC complexes on the cell membrane.

As previously stated, lymphocytes receptors are obtained by random rearrangements of a relatively small number of DNA molecules. This random rearrangement sometimes implies the risk of generating receptors which can bring self-reactive responses (autoimmunity). The way the immune system uses to avoid autoimmunity is to generate new cells clones and to destroy potentially harmful clones thereafter. After initial development in the bone marrow, T cell precursors migrate to the thymus. Positive selection occurs in cortex of the thymus over double positive (CD8 + CD4 +) positive thymocytes, selecting those that are capable of engaging with self peptide-MHC complexes. During positive selection, thymocytes commit to recognize either MHC class I or MHC class II molecules, developing into single positive (SP) cells that express either CD8 or CD4. Those cells can not engage with peptide-MHC complex die by apoptosis (death by neglect). Up to 95% of the cells die by neglect. Subsequently, SP cells migrate to the medulla of the thymus and in the region between the cortex and the medulla they undergo the process of negative selection. SP cells that recognized self-peptide/MHC complexes with high affinity undergo apoptosis. Positive selection guarantee MHC restriction while negative selection provides a mechanism of central tolerance.

Elimination of self-reactive T clones in the thymus (central tolerance) is not 100% efficient. Self-reactive clones that surpass the central tolerance are rendered harmless by a mechanism called "peripheral tolerance". T cell activation depends from antigen presentation of the MHC-peptide complex by APC. Only these cells are able to release the appropriate costimulatory molecules required to completely activate T clones. In lack of these costimulatory molecules, the interaction between a self-reactive T cell and a parenchymal cell brings to the inhibition of the T cell (anergy).

Sometimes a breakdown of the tolerance mechanisms may entitle the appearing of autoimmune diseases. Auto-reactive cells can be activated by foreign micro-organisms that express antigens similar to autologous molecules (antigen mimicry) or as a consequence of the presence of cytokines that have been released to activate other clones, but have the collateral effect to counterbalance the lack of costimulatory molecules needed for anergy.

Allergy is due to a pathological immune response (hypersensitivity) to specific antigens (allergens) contained in food, dust, pollens, animal components, chemical products and drugs.

Recognition of the allergen elicits a Th2 response leading to IgE antibody production and capture by receptors on the surface of mast cells and basophil granulocytes (sensitization phase). Allergen binding then triggers the release from cells of various mediators, such as histamine, prostaglandins and cytokines, which cause the allergic reaction.

The type of reaction is typically related to the mode of entry of allergens, e.g. inhaled pollens cause hay fever with sneezing and cough, while food allergens cause gastrointestinal reactions.

The most severe type of allergic reaction, anaphylactic shock, may result from allergen injection, for example bee stings.

A lack of immune response can be caused either by heritable genetic defects (primary immunodeficiency) or by extrinsic causes as, for example, the HIV infection or drug treatments (secondary immunodeficiencies). The fact that all immunodeficient individuals experience a significant increase in sensitivity to chronic and lethal infections is a clear illustration of the defensive role of the immune system toward microorganisms.

The immune system is capable of responding against anything that is considered as non-self. Transplantation of cells, organs or tissues between unrelated individuals elicits in the recipient a very strong immune response directed against the graft. The cause of tissue incompatibilities within the same species is due to the fact that individuals express unique antigens (alloantigens). Either recipient antibodies or by T cells recognizing donor MHC antigens can be cause of rejection. The solution to this problem is given by immunosuppressive drugs like cyclosporin that block T cell activation and response.

In immunology, the use of mathematical and computational methodologies revealed to be a very important support tool not only for the understanding of the immune system behaviour when dealing with pathogens, tumours and auto-immunity disorders, but also for testing, predicting and optimizing possible treatments for them.

Modelling the Immune System

A model is a mapping from a real-world domain to a mathematical/computational domain; thus, it highlights some of the essential believed properties while ignoring believed unessential ones. Mathematical modelling permits the integration of biological and clinical data at various levels and, in doing so, has the potential to provide insights into complex diseases. Modelling necessitates the statement of explicit hypotheses, a process which improves our understanding of the biological system and can uncover critical points where understanding is still poor. Subsequent simulations can reveal hidden patterns and/ or counter-intuitive mechanisms in complex systems. Theoretical thinking and mathematical modelling help generate new hypotheses that can be tested in the laboratory. Mathematical and computational models are usually designed to improve our understanding of phenomena, to validate or reject hypotheses, to shorten production costs, or to find possible points of intervention in order to drive the behaviour of a system towards given goals.

Of course, such models usually represent coarse sketch of the real biological scenario, however they often demonstrated able to capture the complexity of the biological problem, being able to reproduce the most known important immunological features and to bring out some unknown hidden features.

Models help in finding possible therapeutic targets for many diseases, in optimize existing treatments, in shorten, both in terms of costs and time, the pharmaceutical research and discovery pipeline. Furthermore, a technological revolution is nowadays beginning, as models are starting to be personalized on specific individual data. Patient specific models will allow to use such techniques to reproduce both the immunological background and future of the individual, and to personalize therapeutic and

prophylactic interventions directly on him, achieving better efficacy and minimizing the risk of undesirable effects. This will drive towards what we call a “personalized medicine” scenario.

A good model should be: (1) relevant, capturing the essential properties of the phenomenon; (2) computable, driving computational knowledge into mathematical representation; (3) understandable, offering a conceptual framework for thinking about the scientific domain; and (4) extensible, allowing the inclusion of additional real properties in the same mathematical scheme.

In the framework of the modelling of immune system dynamics, relevant means that the model should be able to capture the essential properties of the system, namely its organization and dynamic behaviour; computable refers to the model's ability to simulate both the dynamic behaviour and the evolution and interactions of system entities; understandable means that the model must reproduce concepts and ideas of immunology while opening new computational possibilities for understanding immune system interactions; finally, extensible refers to the possibility to include new immunology concepts and knowledge with limited effort using the same mathematical and computational framework.

Immunoinformatics represents a multidisciplinary field dealing with experimental immunology and computer science. In particular, it takes advantage of computational approaches that help to understand the overwhelming and complex dynamics of immune system and to face with the enormous amount of data in immunological context.

Recently, immunoinformatics has grown significantly in scientific field and it potentially has the cards to become a discipline of outstanding value. Immunoinformatics involves several subareas that include immunogenomics, immunoproteomics, epitope prediction, in silico vaccination and systems biology approaches applied to immunology. Whereas immunoinformatics aims to develop mathematical and computational methods to study the dynamics of cellular and molecular entities during the immune response (Pappalardo *et al.*, 2015), the immunological bioinformatics focuses on proposing methods to investigate big genomic and proteomic immunological-related datasets and predict new knowledge mainly by statistical inference and machine learning algorithms.

The glut of data produced by high-throughput instrumentation, notably genomics, transcriptomics, epigenetics, and proteomics methods, requires computational tools for acquisition, storage, and analysis of immunological data. The exploitation of such a huge amount of immunological data usually requires its conversion into computational problems, their solution using mathematical and computational approaches, and then the translation of the obtained results into immunologically meaningful interpretations.

Immunogenetics Modelling Approaches

Antibody Modelling

An antibody (Ab) is a protein with a shape depicting a large Y. It is a protein that is released largely by plasma cells. It's a component of the humoral immunity able to make pathogens not harmful. Specifically, the antibody recognizes the antigen expressed by the pathogen or on the cell surface. The Ab binding region is built by a paratope that is specific for one particular epitope on an antigen. As soon as the Ab binds specifically the antigen, the pathogen or the target cell can be killed directly by the Ab or signalled to other specific immune cells for killing.

The specific function of an antibody (Ab), i.e. where it binds and with what affinity, is intimately related to its structure. However, the number of solved Ab structures is tiny compared to the number of known sequences. Given that precisely solving the structure of an Ab (notably using X-ray crystallography) is typically both challenging and time consuming, modelling the structure computationally is a highly-desirable option.

At the time of writing, there are over 2600 Ab structures in the Protein Data Bank (PDB) (see Relevant Website section), of which around 1700 are bound to some kind of ligand (such as protein, peptide and glycan). Even Abs from different species are sufficiently similar that producing homology models of Ab structures with good overall similarity (measured, for example, using the root-mean-square deviation (RMSD) between the α carbons of model and target) is relatively straightforward using standard homology modelling tools, such as Modeller (Webb and Sali, 2014). But low overall RMSD is rarely the end goal of Ab modelling – what matters for nearly all practical applications is that key regions of an Ab are modelled with high accuracy, notably those parts of the Ab responsible for binding to an Ag. In most cases this requires multiple Complementarity-determining regions (CDRs) – which, depending on the definitions used, consist exclusively or predominantly of loops – to be modelled. CDRs are part of the variable chains in immunoglobulins (antibodies) and T cell receptors, generated by B-cells and T-cells respectively. There are three types of CDRs, CDR1, CDR2 and CDR3. Hypervariable regions associated with both immunoglobulins and T cell receptors are found in CDRs. In general, loop modelling is a considerable challenge and becomes increasingly intractable beyond a length of around 8 amino acids (Fiser *et al.*, 2000). CDR3 loops are usually longer than 10 residues and comprise some of V, all of diversity (D, heavy chains only) and joining (J) regions.

Thankfully there are a number of dedicated Ab modelling tools that exploit knowledge of canonical CDR conformations to produce accurate models of most Ab CDRs, at least when conditions are favourable. Example are Pigs (Marcatili *et al.*, 2014), RosettaAntibody (Weitzner *et al.*, 2017). Modelling and docking of antibody structures with Rosetta, and ABodyBuilder (Leem *et al.*, 2016). A typical strategy for such a tool is to choose appropriate template structures from the PDB (often separate templates for the heavy and light chains), graft canonical CDR loops onto the templates (typically good canonical CDR matching will be found for all but CDR-H3), and model the CDR-H3 (either from a template, or *ab initio*).

The accuracy with which tools can generate models of unknown structures has been evaluated via two Antibody Modelling Assessment initiatives, AMA-I (Almagro *et al.*, 2011) and AMA-II (Almagro *et al.*, 2014), at which research groups were given the

task of modelling Ab variable domains of unpublished high-resolution structures. The outcome of AMA-II was positive in several important respects. Accurate models within an RMSD of 1.5 Å are possible with most software for most CDRs and most structures, and higher accuracy is often achievable when someone skilled at modelling is prepared to spend time manually checking and tweaking the model. On the other hand, performance is often poor with Abs from under-represented species and models of the most variable CDR, CDR-H3, are often poor. Given that CDR-H3 is often the most important CDR for Ag binding, this represents a significant problem and an important research topic in its own right (Marks and Deane, 2017).

Even if one has a method capable of generating highly accurate models of unbound Abs, it is not clear how useful that is if one wishes to understand where that Ab binds – even if one has (as is often the case) a solved structure of its known, or likely, Ag. This introduces another challenging problem, that of Ab docking. Protein-protein docking in general has been the subject of the blinded prediction evaluation initiative, CAPRI, since 2002 (Gray *et al.*, 2003). Effective docking commonly involves two key components: the generation of lots of models (decoys) that widely sample the potential “binding space”; and the effective scoring of these models to identify the best decoy. Ab-Ag docking has its own characteristics that make it somewhat different from the more general case – in some respects easier (we know in advance that Abs bind Ags mainly via their CDRs), in other respects potentially more challenging (the CDRs are flexible), and in further respects simply different (Ab contact residues tend to be of different types to those of proteins in general (Brenke *et al.*, 2012). This has led to the development of Ab-specific approaches to docking e.g. SNUGDOCK (Sircar and Gray, 2010), although there appears ample scope for further improvement. In summary, the obstacles to generating a good model of a bound Ab should not be underestimated. However, when circumstances are favourable (which partly depends on the availability of good structural templates), and particularly when an experienced modeller is involved, success is certainly possible.

One context in which there is strong potential to build high quality models of bound Abs is where the model differs only slightly (e.g. by as little as a single residue) from that of a solved structure. Such analyses can be used to infer the impact of mutations to the epitope (e.g. in the context of antigenic escape by an evolving virus) or to the paratope (e.g. where the goal is to engineer a higher-affinity Ab). There are several general approaches for analysing the impact of mutations on the binding between two proteins that can be readily applied to the binding of Ab to Ag. These include online tools such as ANCHOR (Meireles *et al.*, 2010) and mCSM (Pires *et al.*, 2014) that predict changes in the binding affinity between proteins. A much more complex and time-consuming option, but one that has proved remarkably accurate in recent study focusing on broad-spectrum Abs binding to the stalk of influenza A (Lees *et al.*, 2017), is molecular dynamics (MD). MD involves the simulation of molecular forces between atoms and molecules, and can now be performed using relatively modest computational resources through the exploiting of cheap and fast graphical processing units (GPUs). It seems reasonable to assume that MD will make an increasingly important future contribution to the modelling of Abs and Ab/Ag complexes.

Prediction of T- and B-Cell Epitopes

B and T-cells recognize portions within their cognate antigens known as epitopes. The identification of the precise location of these epitopes in antigens is called epitope mapping and is relevant for understanding disease etiology, immune monitoring, developing diagnosis assays and for designing epitope-based vaccines. However, epitope mapping is hampered by the need for experimental testing on large arrays of potential epitope candidates. Luckily, researchers have developed *in silico* prediction methods that dramatically reduce the burden associated with epitope mapping by decreasing the list of potential epitope candidates. Here, we will review some of the most relevant tools for epitope prediction, with special focus on those that are available for free online use.

T-cell epitope prediction

T-cell epitopes are peptide antigens displayed on the surface of antigen-presenting cells (APCs) and bound to major histocompatibility complex (MHC) molecules. MHC molecules fall in two classes, class I (MHC I) and II (MHC II), that are recognized by two distinct sets of T-cells, CD8 T and CD4 T-cells, respectively (Fig. 1). Subsequently, there are two types of T-cell epitopes, CD8 and CD4.

CD8 T-cells become cytotoxic T lymphocytes (CTL) through a priming process that requires the recognition of peptide antigens presented by MHC I molecules on the cell surface of dendritic cells (DC). Thereby, CD8 T-cell epitopes are often known as CTL epitopes. Primed CTLs kill target T-cells displaying their cognate antigens bound to MHC I molecules, thus playing a key role in the clearance of infected and tumoral cells. On the other hand, DC-primed CD4 T-cells become helper (Th) or regulatory (Treg) T-cells that control the immune response through the production of cytokines and cell-to-cell contact.

T-cell epitope mapping consists of isolating the shortest amino acid sequence of an antigen that is able to stimulate either CD4 or CD8 T-cells (Ahmed and Maeurer, 2009). This capacity to stimulate T-cells is called immunogenicity and it is tested in assays requiring synthetic peptides derived from antigens (Ahmad Eweida and El-Sayed, 2016; Malherbe, 2009). There are many distinct peptides within antigens and T-cell prediction methods aim to identify those that are immunogenic. T-cell epitope immunogenicity is contingent on three basic steps: i) antigen processing, ii) peptide binding to MHC molecules and iii) recognition by cognate TCR. Of these three events, MHC-peptide binding is the most selective one at determining T-cell epitopes (Lafuente and Reche, 2009; Jensen, 2007). Therefore, prediction of peptide-MHC binding is the main basis to anticipate T-cell epitopes.

Prediction of peptide-MHC binding

MHC I and MHC II molecules have similar 3D-structures with bound peptides sitting in a groove delineated by two α -helices overlying a floor comprised of eight antiparallel β -stranded sheets (Fig. 2). However, there are also key differences between MHC I

Fig. 1 T-cell epitope recognition (A) Schematic view of T-cell recognition. T cells recognize via T cell receptors (TCR) peptide antigens bound to MHC molecules displayed in the cell surface of antigen presenting cells. CD8 T-cells express CD8 co-receptor that binds to MHC I, while CD4 T-cells express the CD4 co-receptor, which binds to MHC II. (B) Close up of representative 3D-structure of a peptide-MHC I complex recognized by a TCR. MHC I molecule is depicted as green ribbons and the T cell epitope, peptide, in sticks. The TCR α and β chains are shown as blue and green ribbons, respectively, covered by atom surface mesh matching the color of the TCR chains. TCR recognition of peptide-MHC II complexes is similar to that of peptide-MHC I complexes.

Fig. 2 Binding groove of MHC molecules. Figure depicts the molecular surface as seen by the TCR of representative MHC I and II molecules. The binding groove of MHC I molecules is closed while is open in MHC II molecules. As a result, MHC I molecules bind short peptides (8–10 amino acids), while MHC II molecules bind longer peptides (9–22 amino acids).

and II binding grooves that condition peptide-binding predictions. The peptide binding cleft of MHC I molecules is closed as it is made by a single chain. As a result, MHC I molecules can only bind short peptides ranging from 9 to 11 amino acids, whose N- and C-terminal ends remain pinned to conserved residues of the MHC I molecule through a network of hydrogen bonds (Stern and Wiley, 1994; Madden, 1995). The MHC I peptide binding groove also contains deep binding pockets with tight physico-chemical preferences that facilitate binding predictions. There is a complication however. Peptides that have different sizes and bind to the same MHC I molecule often use alternative binding pockets (Madden *et al.*, 1993). Therefore, methods predicting peptide-MHC I binding aim for a fixed peptide length; yet it is generally preferable to predict peptides with nine residues (9-mers) as most MHC I-peptide ligands have that size. In contrast, the peptide-binding groove of MHC II molecules is open, allowing the N- and C-terminal ends of a peptide to extend beyond the binding (Stern and Wiley, 1994; Madden, 1995). As a result, MHC II-bound peptides vary widely in length (9–22 residues), although only a core of nine residues (peptide binding core) sits into the MHC II binding groove. Therefore, peptide-MHC II binding prediction methods generally target to identify these peptide-binding cores. MHC II molecules binding pockets are also shallower and less demanding than those of MHC I molecules. Therefore, peptide-binding prediction to MHC II molecules is less reliable than that of MHC I molecules.

Given the relevance of the problem, there are myriad of methods to predict peptide-MHC binding (**Table 1**). They can be divided in two main categories: data-driven and structure-based methods. Structure-based approaches generally rely on modelling the peptide-MHC structure followed by evaluation of the interaction through methods such as molecular dynamics simulations (Lafuente and Reche, 2009; Desai and Kulkarni-Kale, 2014; Khan *et al.*, 2011; Khan and Ranganathan, 2011, Khan *et al.*, 2010;

^aMethod used for prediction of peptide-MHC binding. Keys for methods: SM: sequence-motif; SB: structure-based; MM: Motif-matrix; QAM: quantitative affinity matrix; SVM: support vector machine; ANN: artificial neural network; QSAR: Quantitative structure–activity relationship model; Combined: Tool uses different methods including ANN and QAM, selecting the more appropriated for each distinct MHC molecule. The table also indicate whether the tool predict supertypes (S), TAP binding (T) and proteosomal cleavage (P); marked with an X.

Tong and Ranganathan, 2013). Structure-based methods have the great advantage of not needing experimental data. However, they are seldom used for they are computationally intensive and could exhibit a lower predictive performance than data-driven methods (Patronov and Doytchinova, 2013).

Data-driven methods for peptide-MHC binding prediction are based on peptide sequences that are known to bind to MHC molecules. These peptides sequences are generally available in specialized epitope databases such as IEDB (Vita *et al.*, 2015), EPIMHC (Molero-Abraham *et al.*, 2014), Antigen (Toseland *et al.*, 2005) and others (Singh and Mishra, 2016). Both MHC I and II binding peptides contain frequently occurring amino acids at particular peptides positions, known as anchor residues. Thereby, prediction of peptide-MHC binding was first approached using sequence motifs (SM) reflecting amino acid preferences of MHC molecules at anchor positions (D'Amaro *et al.*, 1995). However, it was soon shown that non-anchor residues also contribute to the capacity of a peptide to bind to a given MHC molecule (Bouvier and Wiley, 1994; Ruppert *et al.*, 1993). Subsequently, researchers developed motif-matrices (MM) that could evaluate the contribution of each and all peptide positions to the binding with the MHC molecule (Nielsen *et al.*, 2004; Rammensee *et al.*, 1999; Reche *et al.*, 2002; Reche and Reinherz, 2007). The most sophisticated form of motif-matrices consists of profiles (Reche *et al.*, 2002, 2004; Reche and Reinherz, 2007) that are similar to those used for detecting sequence homology (Gribbskov and Veretnik, 1996). Motif-matrices are often confused with quantitative affinity matrices (QAMs) since both produce peptide scores. However, MMs are derived without taking in consideration values of binding affinities and therefore resulting peptide scores are not suited to address binding affinity. In contrast, QAMs are trained on peptides and corresponding binding affinities, and aim to predict binding affinity. The first method based on QAMs was developed by Parker *et al.* (1994) (Table 1). Subsequently, various approaches were developed to obtain QAMs from peptide affinity data and predict peptide binding to MHC I and II molecules (Bui *et al.*, 2005; Nielsen *et al.*, 2007; Peters and Sette, 2005; Stumliolo *et al.*, 1999).

QAMs and motif-matrices assume an independent contribution of peptide-side chains to the binding. This assumption is well supported by experimental data but there is also evidence that neighbouring peptide residues interfere with others (Peters *et al.*, 2003). To account for those interferences, researchers introduced quantitative structure activity relationship (QSAR) additive models wherein the binding affinity of peptides to MHC is computed as the sum of amino acid contributions at each position plus the contribution of adjacent side chains interactions (Guan *et al.*, 2003). However, machine learning (ML) is the most popular and robust approach introduced to deal with non-linearity of peptide-MHC binding data (Lafuente and Reche, 2009). Researchers have used ML for two distinct problems: discrimination of MHC binders from non-binders and prediction of binding affinity of peptides MHC molecules.

For discrimination models, ML algorithms are trained on data sets consisting of peptides that either bind or do not bind to MHC molecules. Relevant examples of ML-based discrimination models are those based on artificial neural networks (ANNs) (Milik *et al.*, 1998; Brusic *et al.*, 1998), support vector machines (SVMs) (Donnes and Kohlbacher, 2005; Bhasin and Raghava, 2004a,b; Jacob and Vert, 2008), decision trees (DTs) (Zhu *et al.*, 2006; Savoie *et al.*, 1999) and Hidden Markov models (HMMs), that can also cope with non-linear data, have also been used to discriminate peptides binding to MHC molecules. However, unlike other ML algorithms, they have to be trained only on positive data. Three types of HMMs have been used to predict MHC-peptide binding: fully connected HMMs (Mamitsuka, 1998), structure-optimized HMMs (Zhang *et al.*, 2006) and profile HMMs (Zhang *et al.*, 2006; Lacerda *et al.*, 2010). Of those, only fully connected HMMs (fcHMMs) and structure-optimized HMMs (soHMMs) can model non-linear data, recognizing different patterns in the peptide binders. In fact, profile HMMs that are derived from sets of ungapped alignments (the case for peptides binding to MHC), are nearly identical to profile matrices (Durbin *et al.*, 1998) (Table 1).

With regard to predicting binding affinity, ML algorithms are trained on datasets consisting of peptides with known affinity to MHC molecules. Both SVMs and ANNs have been used for such purpose. SVMs were first applied to predict peptide binding affinity to MHCI molecules (Liu *et al.*, 2006) and later to MHC II molecules (Jandric, 2016) (Table 1). Likewise, ANNs were also applied first to the prediction of peptide binding to MHC I (Buus *et al.*, 2003; Nielsen *et al.*, 2003) and latter to MHC II molecules (Nielsen and Lund, 2009) (Table 1). Benchmarking of peptide-MHC binding prediction methods appears to indicate that those based on ANNs are superior to those based on QAMs and MMs. However, the differences between the distinct methods are marginal and vary for different MHC molecules (Yu *et al.*, 2002). Moreover, it has been shown that performance of peptide-MHC predictions is improved by combining several methods and providing consensus predictions (Wang *et al.*, 2008).

A major complication for predicting T-cell epitopes through peptide-MHC binding models is MHC polymorphism. In the human, MHC molecules are known as human leukocytes antigens (HLAs), and there are hundreds of allelic variants of class I (HLA I) and class II (HLA II) molecules. These HLA allelic variants bind distinct sets of peptides (Reche and Reinherz, 2003) and hence require specific models for predicting peptide-MHC binding. However, peptide-binding data is only available for a minority of HLA molecules. To overcome this limitation, some researchers have developed pan-MHC specific methods by training ANNs on input data combining MHC residues that contact the peptide with peptide-binding affinity that are capable of predicting peptide-binding affinities to uncharacterized HLA alleles (Nielsen *et al.*, 2007, 2008).

HLA polymorphism also hampers the development of T-cell epitope-based vaccines with wide population coverage as HLA variants are also expressed at vastly variable frequencies in different ethnic groups (Terasaki, 2007). Interestingly, different HLA molecules can also bind similar sets of peptides (Sette and Sidney, 1998, 1999) and researchers have devised methods to cluster them in groups, known as HLA supertypes, consisting of HLA alleles with similar peptide-binding specificities (Doytchinova and Flower, 2005; Greenbaum *et al.*, 2011; Lund *et al.*, 2004). The HLA-A2, HLA-A3, and HLA-B7 are relevant examples of supertypes; 88% of the population expresses at least an allele included in these supertypes (Reche and Reinherz, 2007; Sette and Sidney, 1998, 1999). Identification of promiscuous peptide-binding to HLA supertypes enables the development of T-cell epitope vaccines with high population coverage using a limited number of peptides. Currently, several web-based methods allow the prediction of promiscuous peptide-binding to HLA supertypes for epitope vaccine design including MULTIPRED (Zhang *et al.*, 2011) and PEPVAC (Reche and

Reinherz, 2005) (see Table 1). A method to identify promiscuous peptide-binding beyond HLA supertypes was developed and implemented by Molero-Abraham *et al.* (2013) with the name of EPISOPT. EPISOPT predicts HLA I presentation profiles of individual peptides regardless of supertypes and identifies epitope combinations providing a wider population protection coverage.

Prediction of antigen processing and integration with peptide-MHC binding predictions

Antigen processing shapes the peptide repertoire available for MHC binding and is a limiting step determining T-cell epitope immunogenicity (Zhong *et al.*, 2003). Subsequently, computational modelling of the antigen processing pathway provides a mean to enhance T-cell epitope predictions. Antigen presentation by MHC I and II molecules proceed by two different pathways. MHC II presents peptide antigens derived from endocytosed antigens that are degraded and loaded onto the MHC II molecule in endosomal compartments (Blum *et al.*, 2013). Class II antigen degradation is poorly understood and there is lack of good prediction algorithms yet (Hoze *et al.*, 2013). In contrast, MHC I molecules present peptides derive mainly from antigens degraded in the cytosol. The resulting peptides antigens are then transported to the endoplasmic reticulum by TAP where they are loaded onto nascent MHC I molecules (Blum *et al.*, 2013) (Fig. 3). Prior to loading, peptides often undergo trimming by ERAAP N-terminal amino peptidases (Hammer *et al.*, 2006).

Fig. 3 Class I antigen processing. Figure depicts the major step involved in antigen presentation by MHC I molecules. Proteins are degraded by the proteasome and peptide fragments transported to the endoplasmic reticulum (ER) by TAP before being presented by MHC molecules. TAP transport peptides ranging from 8 to 16 amino acids. Long peptides often become suitable for binding to MCH I molecules after trimming at the N-terminus by ERAAP.

Proteosomal cleavage and peptide-binding to TAP have been studied in detail and there are computational methods to that predict both processes. Proteosomal cleavage prediction models have been derived from peptide fragments generated *in vitro* by human constitutive proteasomes (Nussbaum *et al.*, 2001; Holzthutter *et al.*, 1999) and from sets of MHC I restricted ligands mapped onto their source proteins (Nielsen *et al.*, 2005; Diez-Rivero *et al.*, 2010a,b; Bhasin and Raghava, 2005). On the other hand, TAP binding prediction methods have been developed by training different algorithms on peptides of known affinity to TAP (Bhasin and Raghava, 2004a,b; Diez-Rivero *et al.*, 2010a,b; Daniel *et al.*, 1998; Brusic *et al.*, 1999). Combination of proteosomal cleavage and peptide-binding to TAP with peptide-MHC binding predictions increases T-cell epitope predictive rate in comparison to just peptide-binding to MHC I (Donnes and Kohlbacher, 2005; Tenzer *et al.*, 2005; Bhasin and Raghava, 2004a,b; Doytchinova *et al.*, 2006; Larsen *et al.*, 2005). Subsequently, researchers have developed resources to predict CD8 T-cell epitopes through multistep approaches integrating proteosomal cleavage, TAP transport and peptide-binding to MHC molecules (Reche *et al.*, 2004; Donnes and Kohlbacher, 2005; Doytchinova *et al.*, 2006; Larsen *et al.*, 2005; Schubert *et al.*, 2015, 2016; Rammensee *et al.*, 1995) (Table 1).

T-cell epitope prediction concluding remarks

Current peptide-MHC binding predictions methods can readily anticipate T-cell epitopes from primary sequences. However, while it is possible to verify experimental binding data for most peptides predicted to bind to MHC molecules, only ~10% of those are shown to be immunogenic (able to elicit a T-cell response) (Zhong *et al.*, 2003). This scenario remains true when using T-cell epitope predictions methods that combine models for all the steps that determine T-cell epitope immunogenicity. Such a low T-cell epitope discovery rate is due to the fact that we do not have adequate models for antigen processing. In order to accelerate epitope identification and translational vaccine research, we must improve epitope immunogenicity prediction and define rationales and platforms for prioritizing protein antigens in epitope prediction and vaccine design (Flower *et al.*, 2010; Diez-Rivero and Reche, 2012; Molero-Abraham *et al.*, 2015). An alternative approach to overcome the lack of immunogenicity of predicted T-cell epitopes is to combine legacy experimentation, consisting of experimentally defined epitopes, with immunoinformatics predictions. This strategy was first conceived to assemble CD8 T-cell epitope vaccines (Reche *et al.*, 2006; Molero-Abraham *et al.*, 2013) and later extended to CD4 T-cell epitope vaccines (Sheikh *et al.*, 2016). Key criteria for epitope inclusion/selection are conservation and binding to multiple MHC molecules for maximum population protection coverage.

B-cell epitope prediction

B-cells recognize solvent exposed antigens through antigen receptors, B-cell receptor (BCR), consisting of membrane-bound immunoglobulins (Fig. 4). Upon activation, B-cells differentiate and secrete soluble forms of the immunoglobulin, also known as antibodies. A B-cell epitope or antigenic determinant is the antigen portion binding to the immunoglobulin or antibody. Antigens recognized by B-cells can be of different chemical nature but most of them are proteins and here will focus on them.

Any solvent exposed region in the antigen can be subject of recognition by antibodies. Nonetheless, B-cell epitopes can be divided in two main groups: linear and conformational (Fig. 5). Linear B-cell epitopes consist of sequential residues, peptides, whereas conformational B-cell epitopes consist of patches of solvent exposed atoms from residues that are not necessarily sequential (Fig. 5). Therefore, linear and conformational B-cell epitopes are also known as continuous and discontinuous B-cell epitopes, respectively. Antibodies recognizing linear B-cell epitopes can recognize denatured antigens, while denaturing the antigen results in loss of recognition for conformational B-cell epitopes. Most B-cell epitopes (approximately a 90%) are conformational and in fact only a minority of native antigens contains linear B-cell epitopes (Van Regenmortel, 2009).

B-cell epitopes are determined by structural studies that require solving the 3D-structure of antigen-antibody complexes using X-ray crystallography, nucleic magnetic resonance (NMR) or electron microscopy (EM). Alternatively, B-cell epitopes can be identified by functional assays in which the antigen is mutated and the interaction antibody-antigen is evaluated and by screening

Fig. 4 Antigen-antibody interaction. B-cell epitopes are solvent exposed portions of the antigen that bind to immunoglobulins and antibodies. The portion of the antibody recognizing the epitope is known as paratope.

Fig. 5 Linear and conformational B-cell epitopes. Linear B-cell epitopes are composed of sequential/continuous residues, while conformational B-cell epitopes contain scattered/discontinuous residues along the sequence.

of peptide libraries for antibody binding (Potocnakova *et al.*, 2016). B-cell epitope prediction aims to facilitate B-cell epitope identification with the practical purpose of replacing the antigen for antibody production or for carrying structure-function studies.

Prediction of linear B-cell epitopes

For Linear B-cell epitopes are peptides they can easily be used to replace antigens for antibody production. Therefore, despite being a minority, prediction of linear B-cell epitopes has received major attention. Linear B-cell epitopes are predicted from the primary sequence of antigens using sequence-based methods. Early computational methods for the prediction of B-cell epitopes were based on simple amino acid propensities scales depicting physico-chemical features of B-cell epitopes. For example, Hoop and Wood applied residue hydrophilicity calculations for B-cell epitope prediction (Hopp and Woods, 1981, 1983) on the assumption that hydrophilic regions are predominantly located on the protein surface and are potentially antigenic. We know now however that protein surfaces contain roughly the same number of hydrophilic and hydrophobic residues (Lins *et al.*, 2003). Other amino acid propensity scales introduced for B-cell epitope prediction are based on flexibility (Karplus and Schulz, 1985), surface accessibility (Emini Hughes *et al.*, 1985) and β -turn propensity (Pellequer *et al.*, 1993). Current available bioinformatics tools to predict linear B-cell epitopes using propensity scales include PREDITOP (Pellequer and Westhof, 1993) and PEOPLE (Alix, 1999) (Table 2). PREDITOP (Pellequer and Westhof, 1993) uses a multi-parametric algorithm based on hydrophilicity, accessibility, flexibility and secondary structure properties of the amino acids. PEOPLE (Alix, 1999) uses the same parameters and in addition include the assessment of β -turns. A related method to predict B-cell epitopes was introduced by Kolaskar and Tongaonkar (Kolaskar and Tongaonkar, 1990) consisting of a simple antigenicity scale derived from physicochemical properties and frequencies of amino acids in experimentally determined B-cell epitopes. This index is perhaps the most popular antigenic scale for B-cell epitope prediction and it is actually implemented by GCG (Womble, 2000) and EMBOSS (Rice *et al.*, 2000) packages.

Comparative evaluations of propensity scales carried out on a dataset of 85 linear B-cell epitopes showed that most propensity scales predicted between 50%–70% of B-cell epitopes, with the β -turn scale reaching the best values (Pellequer *et al.*, 1993, 1991). It has also been shown that combining the different scales does not appear to improve the predictions (Pellequer and Westhof, 1993; Odorico and Pellequer, 2003). Moreover, Blythe and Flower (Blythe and Flower, 2005) demonstrated that single-scale amino acid propensity scales are not reliable to predict epitope location.

Poor performance amino acid scales for prediction of linear B-cell epitopes prompted the introduction of machine learning (ML)-based methods (Table 3). These methods are developed by training ML algorithms to distinguish experimental B-cell epitopes from non-B-cell epitopes. Prior to training B-cell epitopes are translated into features vectors capturing selected properties, such as those given by different propensity scales. Relevant examples of B-cell epitope prediction methods based on ML include BepiPred (Jespersen *et al.*, 2017), ABCpred (Saha and Raghava, 2006), LBtope (Singh *et al.*, 2013), BCPREDS (El-Manzalawy *et al.*, 2008) and SVMtrip (Yao *et al.*, 2012). Datasets, training features and algorithms used for developing these methods differ. BepiPred is based on random forests trained on B-cell epitopes obtained from 3D-structures of antigen-antibody complexes (Jespersen *et al.*, 2017). Both BCPREDS (El-Manzalawy *et al.*, 2008) and SVMtrip (Yao *et al.*, 2012) are based on support vector machines (SVM) but while BCPREDS was trained using various string kernels that eliminate the need for representing the sequence into fix length feature vectors, SMVtrip was trained on fix length tripeptide composition vectors. ABCpred and LBtope methods consist of artificial neural networks (ANN) trained on similar positive data, B-cell epitopes, but differ on the negative data, non B-cell epitopes. Negative data used for training ABCpred consisted on random peptides while negative data used for LBtope

consisted of experimentally validated non B-cell epitopes form IEDB (Vita *et al.*, 2015). In general, B-cell epitope prediction methods based on ML-algorithm are reported to outperform those based on amino acid propensity scales. However, some authors have reported that ML algorithms show little improvement over single scale-based methods (Greenbaum *et al.*, 2007).

Prediction of conformational B-cell epitopes

Most B-cell epitopes are conformational and yet, prediction of conformational B-cell epitopes has lagged behind that of linear B-cell epitopes. There are two main practical reasons for that. First of all, prediction of conformational B-cell epitopes requires in general knowing the protein three-dimensional (3D)-structure and this information is only available for a fraction of the proteins (Levitt, 2009). Secondly, isolating conformational B-cell epitopes from their protein context for selective antibody production is a difficult task that requires suitable scaffold for epitope grafting (Levitt, 2009). Thereby, prediction of conformational B-cell prediction is currently of little relevance for epitope-vaccine design and antibody-based technologies. Nonetheless, prediction of conformational B-cell epitopes is relevant for carrying structure-function studies involving antibody-antigen interactions.

Table 3 A summary list of the best-known and recent databases relevant in immunology research

Databases	Description	References
AAgAtlas http://aagatlas.ncpsb.org	Human autoantigen database	Wang <i>et al.</i> (2017)
ALPSbase http://www.niaid.nih.gov/topics/alps/Pages/default.aspx	Autoimmune lymphoproliferative syndrome database	Puck (2005)
AntigenDB http://www.imtech.res.in/raghava/antigen	Sequence, structure and other data on pathogen antigens	Ansari <i>et al.</i> (2010)
AntiJen http://www.ddg-pharmfac.net/antijen/AntiJen/antijenhomepage.htm	Quantitative binding data for peptides and proteins of immunological interest	Toseland <i>et al.</i> (2005)
BCIpep http://www.imtech.res.in/raghava/bcipep/	Database of experimentally determined B-cell epitopes of antigenic proteins	Saha <i>et al.</i> (2005)
bNAber http://bnaber.org/	A database of broadly neutralizing HIV – 1 antibodies	Eroshkin <i>et al.</i> (2014)
dbMHC http://www.ncbi.nlm.nih.gov/gv/mhc/	dbMHC provides access to HLA sequences, tools to support genetic testing of HLA loci, HLA allele and haplotype frequencies of over 90 populations worldwide	Helmberg <i>et al.</i> (2004)
DIGIT http://circe.med.uniroma1.it/digit	Database of immunoglobulin variable domain sequences annotated with the type of antigen, the germline sequences and pairing information between light and heavy chains	Chailyan <i>et al.</i> (2012)
EPIMHC http://imed.med.ucm.es/epimhc/	A curated database of MHC-binding peptides for customized computational vaccinology	Reche <i>et al.</i> (2005)
Epitome http://roslab.org/services/epitome/	Database of all known antigenic residues and the antibodies that interact with them	Schlessinger <i>et al.</i> (2006)
GPX-Macrophage Expression Atlas http://gpxmea.gti.ed.ac.uk/	An online resource for expression based studies of a range of macrophage cell types following treatment with pathogens and immune modulators	Grimes <i>et al.</i> (2005)
HaptenDB http://www.imtech.res.in/raghava/haptendb	Database of hapten molecules, small molecule not immunogenic by itself, that can react with antibodies of appropriate specificity	Singh <i>et al.</i> (2006)
HPTAA http://www.bioinfo.org.cn/hptaa/	Database of potential tumor-associated antigens that uses expression data from various expression platforms, including carefully chosen publicly available microarray expression data, GEO SAGE data and Unigene expression data	Wang <i>et al.</i> (2006)
IEDB http://www.iedb.org/	The Immune Epitope Database (IEDB) provides a catalog of experimentally characterised B and T cell epitopes, as well as data on MHC binding and MHC ligand elution experiments	Vita <i>et al.</i> (2015)
EDB – 3D http://www.immuneepitope.org/bb_structure.php	Structural data within the Immune Epitope Database	Ponomarenko <i>et al.</i> (2011)
IL2Rgbase http://research.nhgri.nih.gov/scid/	X-linked severe combined immunodeficiency mutations	Puck (1996)
IMGT http://www.imgt.org/	The international ImMunoGeneTics information system (iMGT) is a high-quality integrated knowledge resource specialized in IG, T cell receptors and MHC of human and other vertebrate species and related proteins of the immune system (RPI)	Lefranc <i>et al.</i> (2005)
IMGT/GENE-DB http://www.imgt.org/IMGT_GENE-DB/GENEelect?livret=0/	IMGT/GENE-DB is part of IMGT database and allows a search of IG and TR gene entries by locus, group, subgroup, based on the classification axiom of IMGT-ONTOLOGY	Giudicelli and Lefranc (1999)
IMGT/HLA http://www.ebi.ac.uk/imgt/hla/	Database of recognized HLA alleles and their sequences for performing sequence alignments	Robinson <i>et al.</i> (2000)
IMGT/LIGM-DB http://www.imgt.org/ligmdb/	IMGT/LIGM-DB is a database of immunoglobulin and T cell receptor nucleotide sequences	Giudicelli <i>et al.</i> (2006)
IMGT/mAb-DB http://www.imgt.org	Database for therapeutic monoclonal antibodies	Lefranc <i>et al.</i> (2015)
ImmuNet http://immunet.princeton.edu	Database of immunological networks and functional relationships between molecular entities, able to predict disease-associated genes	Gorenshteyn <i>et al.</i> (2015)
InnateDB http://www.innatedb.com/	Database of genes, proteins, experimentally-verified interactions and signalling pathways involved in the innate immune response of humans, mice and bovines to microbial infection	Lynn <i>et al.</i> (2008)
Interferon Stimulated Gene Database http://www.lerner.ccf.org/labs/williams/xchip-html.cgi	A database of interferon stimulated genes (ISGs)	Samarajiwa <i>et al.</i> (2009)
IPD - Immuno Polymorphism Database http://www.ebi.ac.uk/ipd/	Databases of polymorphic genes in the immune system	Robinson <i>et al.</i> (2003)

VBASE2 http://www.vbase2.org/	Database of germ-line V genes from the immunoglobulin loci of human and mouse	Retter <i>et al.</i> (2005)

There are several methods available to predict conformational B-cell epitopes (Table 2). The first to be introduced was CEP (Kulkarni-Kale *et al.*, 2005) which relied almost entirely on predicting patches of solvent exposed residues. It followed DiscoTope (Haste Andersen *et al.*, 2006), which in addition to solvent accessibility, considered amino acid statistics and spatial information to predict conformational B-cell epitopes. An independent evaluation of these two methods using a benchmark dataset of 59 conformational epitopes revealed that they did not exceed 40% of precision and 46% of recall (Ponomarenko and Bourne, 2007). Subsequently, more methods were developed like ElliPro (Ponomarenko *et al.*, 2008), that aims to identify protruding regions in antigen surfaces, and PEPITO (Sweredoski and Baldi, 2008) and SEPPA (Sun *et al.*, 2009) that manage to combine single physicochemical properties of amino acids and geometrical structure properties. The reported Area Under the Curve (AUC) of these methods is around 0.7, which is indicative of poor discrimination capacity yet better than random. However, in an independent evaluation SEPPA reached an AUC of 0.62 while all the mentioned methods had AUC around 0.5 (Xu *et al.*, 2010). ML has also been applied to predict conformational B-cell epitopes in 3D-structures. Relevant examples include EPITOPIA (Rubinstein *et al.*, 2009) and EPSVR (Liang *et al.*, 2010) which are based on naïve bayes and support vector regression, respectively, train on features vectors combining different scores. The reported AUC of these two methods is around 0.6.

The above methods for conformational B-cell epitope prediction identify generic antigenic regions regardless of antibodies that are ignored. However, there are also methods for antibody-specific epitope prediction (Sela-Culang *et al.*, 2015b). This approach was pioneered by Soga *et al.* (2010) who defined an antibody-specific epitope propensity (ASEP) index after analysing the interfaces of antigen-antibody 3D-structures. Using this index, they developed a novel method of predicting epitope residues for individual antibodies that worked by narrowing down candidate epitope residues predicted by conventional methods. More recently Krawczyk *et al.* (2014) developed EpiPred, a method that uses a docking like approach to matchup antibody-antigen structures and thus identify epitope regions on the antigen. A similar approach is used by PEASE (Sela-Culang *et al.*, 2015a) only that the method utilizes the sequence of the antibody and the 3D-structure of the antigen. Briefly, for each pair of antibody sequence and antigen structure, PEASE uses a machine-learning model trained on properties from 120 antibody-antigen complexes to identify pair combination of residues from CDRs of the antibody and the antigen that are likely to interact.

Another method to identify conformational B-cell epitopes in a protein with a known 3D structure is through mimotope-based methods. Mimotopes are peptides selected from randomized peptide libraries for their ability to bind to an antibody raised against a native antigen. Mimotope-based methods require as input antibody affinity-selected peptides and the 3D structure of antigen. Examples of bioinformatics tools for conformational B-cell epitope prediction using mimotopes include MIMOX (Huang *et al.*, 2006), PEPITOPE (Mayrose *et al.*, 2007), EPISEARCH (Negi and Braun, 2009), MIMOPRO (Chen *et al.*, 2011) and PEPMAPPER (Chen *et al.*, 2012) (Table 2).

Methods for conformational B-cell epitope prediction require the 3D-structure of the antigen. Exceptionally, however, Ansari and Raghava (2010) developed a method (CBTOPE) for the identification of conformational B-cell epitope from the primary sequence of the antigen. CBTOPE is based on SVM trained on physicochemical and sequence-derived features of conformational B-cell epitopes. CBTOPE reported accuracy was 86.6% in cross-validation experiments.

B-cell epitope prediction concluding remarks

Prediction B-cell epitopes is clearly relevant for epitope-vaccine design and for developing pharmaceutical and biotech applications based on antibody-antigen interactions. As a result, there are many methods available to predict both conformational and linear B-cell epitopes. However, practical application of B-cell epitope prediction has seldom arrived for different reasons. First of all, prediction of B-cell epitopes is still unreliable for both linear and conformational B-cell epitopes. Secondly, linear B-cell epitopes do usually elicit antibodies that do not cross-react with native antigens. Third, the great majority of B-cell epitopes are conformational and yet predicting conformational epitopes has few applications, as they cannot be isolated from their protein context. Under this scenario, it is key to improve current methods for B-cell epitope prediction and more importantly to develop approaches and platforms for epitope grafting onto suitable scaffolds capable of replacing the native antigen.

Modelling Signalling Pathways in Immunology

The study of immunology includes also the study of immune signalling networks (Dower and Qvarnstrom, 2003). Immunological networks oscillate from the macro to the micro level and within this range the breadth of computational tools co-adjuvate both in vitro and in vivo studies (Kidd *et al.*, 2014).

Several signalling pathway components, such as kinases, phosphatases, adaptor molecules and molecular scaffolds are essential to orchestrate extracellular signals with distinct cellular function. In immune context, cellular signalling leads to the activation of different cells owing specific immune activities (Harwood and Batista, 2010; Kawai and Akira, 2011). Specific ligands bind to a specific receptor on the cellular membrane of an immune system cell to trigger biochemical reactions and signal transduction pathways. Cytokines are secreted by immune cells in response to cellular signalling; they bind to specific membrane receptors to propagate the signal through second messengers, such as tyrosine kinase complexes, with the aim to modify cellular activity and regulate gene expression (Turnera *et al.*, 2014). Interleukins represent the largest class of cytokines and are secreted by a specific leukocyte that indirectly acts on other ones recruited as signalling ligands.

Understanding and targeting these networks may be the key for the development of novel immunomodulatory therapies and the treatment of immune dysfunction and dysregulation disorders. Graph theory (Biggs *et al.*, 1986) and dynamical modelling (Banks *et al.*, 2017) represent two major computational approaches used to study signalling networks (Janes and Lauffenburger, 2013). Both approaches result useful: specifically, network analysis and graph theory improve the understanding of signalling network architecture and organization, and predict the information-processing capabilities of the model through statistical methods, whereas dynamical modelling is helpful to determine how the entire system varies in time and space upon receiving specific and simultaneous stimuli, such as in cross-talk phenomena. Dynamic modelling approaches can be divided in two classes: deterministic and stochastic models. Deterministic models usually use ordinary differential equations (ODEs) based systems of biochemical interactions. Stochastic models use Gillespie's algorithm as the standard approach for computations (Gillespie, 2007).

A new computational approach could be represented by a combination of methodologies consisting of agent-based technique implemented with signalling metabolic pathway analysis. A combination model like this, could be considered exemplary in precision medicine due to the fact that these models own the potential to create therapeutic protocols tailored to a patient's specific biology, needs and health conditions. Indeed, it could be used to better understand the pathogenic mechanisms of autoimmune disease such as multiple sclerosis disorder and to suggest predictive information capabilities. The latter concerns the effectiveness of drugs in typical sclerosis multiple's patient scenario, according to his/her own genetic risk factors, anamnesis, average number and typologies of relapses. To facilitate the design and the simulation of the dynamics of immune system related signalling pathways, specific software like Complex Pathways Simulator (COPASI), may help to this aim (Hoops *et al.*, 2006).

Tools for Modelling Cellular Immune System Dynamics

During the years, many models and tools have been developed to mimic the immune system functions at the cellular scale. However, all the adopted strategies can be grouped in two main approaches: the top-down and the bottom-up approaches.

The first approach is represented by so-called top-down approach. The top down approach works by looking down from above to the problem and estimates the behaviour at the macroscopic level. This is usually obtained by the use of Differential Equations (DE). The DE-based models are all population-based, and the spatiality and topology which both depend on individual interactions are, in general, ignored. Historically, the first models that have been developed for representing the immune system function at the cellular scale make use of such an approach thanks to the possibility to borrow the well-established mathematical techniques widely used for engineering, mathematics and physics. The simplest models based on the top-down approach make use of Ordinary Differential Equations (ODE). For very simple ODE models it is possible to take advantage of years of mathematical studies and methods that can bring out analytical solutions, steady states and asymptotic behaviour. However, as the biological description grows, they become almost intractable and can be only solved numerically. The application of some extension, such as the use of Partial Differential Equations (PDE) can bring some spatial description, whereas the use of stochastic differential equations (SDE) and delayed differential equations (DDE) can allow to reproduce stochastic effects and temporal delays, respectively. However, all of these usually entitle instability problems, a higher computational effort and numerical simulations only. Another problem of differential equations is given by their formalism. The mathematical "language" used is not

commonly known to biologists, making the communication with mathematicians/computer scientists even hard, and damaging the interdisciplinary collaboration. Despite of that, models based on differential equations have been successfully used for years bringing out important results and helping in understanding, verifying and validating the basic concepts of immunology.

Many equation-based models have been presented in the literature. In the field of tumor immunology, a simple model for effector cells and tumor cells has been defined by Kuznetsov and co-workers (Kuznetsov *et al.*, 1994). In their model, a threshold above which there is uncontrollable tumor growth is predicted. Below such threshold, the disease can be attenuated with periodic exacerbations occurring every 3–4 months. DeLisi and Rescigno (1977) and Adam (1996) take also into account, besides of IS populations and tumor cells, the external stimulation of immune cells, showing that such a stimulation may increase survival. On the other hand, it has been possible to show that, in some particular scenario, an increase in the number of effector cells may increase the chance of tumor survival. Nani and Ögütörel (1994) include adoptive cellular immunotherapy in their model against tumor growth. This model takes into account stochastic effects (SDE) on the IS-cancer interactions, showing that success of treatment is dependent on the initial tumor burden. Kirschner and co-workers (Kirschner and Webb, 1997) used several differential equations to demonstrate the progression HIV infection by including some important characteristics of the pathology as well as the effects of a combined drug therapy. The model by Nowak *et al.* (1991) indicated that virus diversity is able to speed up the infection progress of HIV.

Gullo *et al.* (2015) developed an ODE model for predicting and improving the expansion of human cord blood CD133 + hematopoietic stem/progenitor cells. In this model, no pathology is reproduced. The combined effects (survival, duplication and differentiation) of different cytokines combinations on progenitor stem cells are instead predicted to suggest the best cytokine combination that maximizes duplication, while minimizing differentiation towards other cell populations. Another example of the immune system – tumor interaction under the actions of an external stimulus can be found in the work by Bianca *et al.* (2012). In their model the authors describe with sufficient degree of detail both the humoral and cellular response of the immune system to the tumor associated antigens and the recognition process between B cells, T cells and antigen presenting cells. The control of the tumor cells growth occurs through the definition of different vaccine protocols with good agreement with in vivo experiments on transgenic mice.

The bottom-up approach works at the opposite side by observing the entities behaviour individually, and thus representing the system at a lower, microscopic level. With the bottom-up approach, unexpected complex global properties can “emerge” as the sum of the rather simple individual behaviours (emergent properties). This approach usually requires greater computational power in order to simulate a significant number of entities, and for this reason it has been pushed only in the last years following the gains in computational performance achieved in the computer world. Cellular automata (CA) and (Multi)Agent-based methods are the most used bottom-up approaches.

CA are composed by a set of identical elements, called cells, each of one occupying a node of a regular and discrete spatial network (a lattice of n -tuples of integer number). The possible states of a cell are discrete and belong to a finite set of states. CA evolve using discrete time steps, and all cells change their states according to a local rule δ (or transition function) homogeneously applied at every step which depends on cell state itself and on the state of the cells in the neighbourhood. The CA-based approach was adopted to reproduce the IS behaviour mainly to study their ability to self-adapt and regulate. In this field, the papers by Santos (1999) and Hershberg *et al.* (2001) showed how, with CA, it was possible to study the HIV-immune dynamics in physical space and Shape Space, respectively. Grilo *et al.* (1999) combined of Genetic Algorithms and CA to represent the dynamical changes that may occur in the virus - the immune cells equilibrium. In Beauchemin *et al.* (2005), Beauchemin and co-workers present a simple two-dimensional CA model of influenza infection. CA have been also used to reproduce the IS-Tumor interactions (Mallet and De Pillis, 2006). Other CA-based models for the IS can be found in Bandini (1996), Hu and Ruan (2003) and Perelson (2002).

Agent based models can be seen as an extension of CA. ABM suppose the presence of individuals (agents) that are usually placed on a simulation space (i.e. a lattice). Such agents can be of heterogeneous nature, can have internal properties (i.e. lifetime, internal state and energy), and can act and take decisions (i.e. move, interact with other agents in their neighbourhood, modify their internal state or die) individually or as a result with the interaction with other agents. Models based on CA and ABM have various advantages. By definition, they can be stochastic and include both delays and a spatial description. Furthermore, they allow a richer description of the biological aspects. As a consequence of that, approximations are usually more biological in character than mathematical. Nonlinearities are managed easily and it is always possible to add complexity or modify the model without introducing any new difficulties in solving it. Such methods are also intrinsically numerically stable thanks to the fact that most of the variables representing the attributes of the entities are integers and very few floating point operations are required.

Guo and co-workers validated the three stages of HIV infection by using a multi-agent model (Guo *et al.*, 2005). Perrin and co-workers emphasized the diversity and mutation of HIV virus, which are important characteristics that influence the immune response latency (Perrin *et al.*, 2006). Jacob *et al.* (2004) presented a swarm-based, three-dimensional model for the human immune system, innate response and adaptive response. The model takes on a strengthening reaction to the previous encountering pathogen, giving a simple representation of immune memory mechanisms.

C-IMMSIM and SIMTRIPLEX are ABM models developed in the C programming language (Bernaschi and Castiglione, 2001; Palladini *et al.*, 2010), with focus on improved efficiency and simulation size and complexity. These simulators, initially developed for HIV and mammary carcinoma, respectively, mimic the receptor interactions by using binary strings. Many mechanism of the immune system (i.e., memory, specificity, tolerance, homeostasis etc.) are here represented. In these simulators, the IS response is designed and coded to allow simulations considering millions of cells with a very high degree of complexity.

The same computational framework developed with SimTriplex has been also used to predict the effects of candidate vaccine adjuvants derived by citrus in boosting the immune system activation (Pappalardo *et al.*, 2016), to investigate the induced immune system response against B16-melanoma (Pappalardo *et al.*, 2011), and, when combined in a hybrid fashion with a lattice Boltzmann (an equation based method), to model the avascular tumor growth under nutrient diffusion, also including the relative immune response (Alemani *et al.*, 2012). SIMMUNE investigates how context adaptive behaviour of the IS might emerge from local cell-cell and cell-molecule interactions (see Relevant Websites section). It is based on molecule interactions on a cells surface. Cells do not have states but behaviours that depend on rules based on cellular response to external stimuli. CYCELLS (Warrender *et al.*, 2006), designed for studying intercellular interactions, uses a hybrid model that represents molecular concentrations continuously and cells discretely. Each type of molecular signal (e.g. cytokines) is represented by a decay and diffusion rate.

Finally, ABM specific development tools have also been used to model the Immune system behaviour, as in the model by Pennisi *et al.* (2013). In their work the authors use an ABM development framework named NetLogo to reproduce the complex cross regulation mechanisms that occur between CD8 T cells and T regulatory cells and show how the appearing of relapsing-remitting multiple sclerosis can occur in predisposed patients that also present breakdown of such regulatory functions.

In the last few years also Petri Nets (PN) have been applied to catch up the immune system dynamics. PN are graphical modelling tool initially developed to reproduce the behaviour of concurrent distributed systems. PN include some graphical elements such as places (represented by empty circles) to represent the possible states of a system, transitions (represented by boxes) to represent possible changes in the states of the system, and arrows to connect places to transitions and vice-versa. Inside places we can find the tokens (small black spheres) to quantify the occurrences or the number of elements in given state. The happening of an event is described by the fact that tokens are taken from input places and consumed by transitions, that can then produce some new tokens in the output places according to well-defined rules. Many analytical methodologies for studying the properties of a PN model have been also presented. A brief summary of PN related methodologies can be found in Murata (1989).

PN have been increasingly applied in other fields of engineering, computer science, chemistry and, lastly, in biology for modelling signalling pathways. Their application to model the immune system function is relatively new and shows how it is possible to apply a particular extension of PN (the Fuzzy continuous PN) for the modelling of the Immune system response (Park *et al.*, 2006). However, such an approach presented some flaws; among them, the biggest one was represented by the fact that it did not allow to distinguish among different kind of cells that have different internal states, receptors, or a different position in the simulation space.

Recently, Pennisi and co-workers presented a novel methodological approach based on Coloured Petri Nets (CPN) to model the immune system function (Pennisi *et al.*, 2016). CPN associate “colours” to tokens. Colours can describe token specific properties and/or internal states (i.e., life-time, position, receptor) and then it is possible to discern among tokens with different internal states. Through a simple example model of the humoral immune system response that was able to represent some of the most complex features of the adaptive IS response like memory and specificity, such a methodology demonstrated able to allow a good level of granularity in the description of cells behaviour, without losing the possibility to have some sort of qualitative analysis, and thus positioning itself somewhat in the middle between top-down and bottom-up approaches.

Immunological Databases

Over recent years database resources have become a fundamental tool for immunological research, due to the growing explosion of extensive information from advanced biotechnology that produce large amounts of biological data. The access to immunological databases is increasingly widespread in immunological research for extracting existing information, planning experiments and analysing experimental results. Immunological data include biological sequences, antigenic and epitope structures, immunogenetic properties and specificity of immune interactions. Immunological databases include both bioinformatic resources in which immunological data are stored and computational methodologies suitable for the extraction and the analysis of information data. These tools have become increasingly sophisticated to allow a speed up of the discovery process, a quick identification of sequences of interest and an achievement of significant bibliographic, taxonomic and feature information.

Repertoire Sequencing

The advent of comparatively cheap Next Generation Sequencing (NGS) is transforming many areas of biology, and immunology is no exception. NGS is a term used to describe a number of high-throughput sequencing technologies that typically generate large numbers of fairly short reads spanning part of a longer nucleic acid sequences. There are many potential applications in this field, ranging from the identification of polymorphisms in immune-related genes, to understanding how rapidly-mutating viruses evolve within a single individual in response to host immune pressure. But many of the most interesting and challenging applications involve characterizing the properties of T-cell and/or B-cell repertoires by sequencing the genomic DNA or messenger RNA that encodes individual TCRs and Abs, a technique known as Rep-seq. The discussion here focuses on Ab repertoire sequencing in order that the additional complexities associated with somatic hypermutation can be discussed, but in other respects the similarities with T-cell repertoire sequencing are considerable.

Ideally, we would like to capture the whole repertoire – paired, full-length sequences of Abs – at sufficiently frequent intervals to elucidate the dynamic properties of interest (potential applications are considered below), but there are important practical

limitations. Firstly, there are limits to what proportion of the repertoire is present in a biological sample – only around 2% of the full human repertoire is found in peripheral blood, the commonest type of sample (much larger proportions are present in lymph nodes and spleens). Secondly, the choice of sequencing platform affects both read length and depth-of-coverage (i.e. the number reads spanning a given base in the target sequence). Here it is worth considering the specific challenges posed by Ab repertoires as targets for NGS.

Standard RNA-seq with paired-end read lengths of around 100 (2×50) or 150 (2×75) nucleotides is the norm for genomic studies. These short sequences are then assembled, often using a reference genome, into full-length sequences. However, the pattern of variability within a typical set of Ab sequences – with highly variable regions (the CDRs) separated by less variable regions (the framing regions) – means that naïve approaches to sequence assembly risk generating large numbers of chimeric artefacts, i.e., sequences that do not exist *in vivo*. For this reason, Rep-seq is generally undertaken using reads that are long enough to span all, or most, of the region of interest – which, for the heavy chain, spans all three CDRs and, for some applications, the part of the constant region that determines Ab isotype. In practice, many different read-lengths have been used with 600 (2×300) nucleotides (Illumina MiSeq) arguably the most popular current option. Although no assembly is required, this length is still shorter than one would choose, as it means that the 5' end of each read starts within a comparatively variable region of the Ab sequence. To address this problem, it is typically necessary to use a large set of V-gene-specific primers.

Given the high diversity of Ab sequences, a further challenge arises from the combination of sequencing depth constraints and sequencing error rates (approximately 2.5×10^6 reads per sample and 10^{-4} per base respectively with Illumina MiSeq). The number of reads is much lower than the actual repertoire diversity; in practice, this means that it is impossible to distinguish between a true sequence polymorphism observed only once and a sequence error. This problem can be partially solved by adding a molecular barcode to each sequence prior to PCR amplification; sequences containing errors that share the same barcode (and hence should be identical) can then be combined to form the correct consensus sequence.

One additional, and crucial, limitation is that standard sequencing platforms fail to retain information about the pairing of heavy and light Ab chains. New technologies are emerging that address this issue using microfluidic single-cell technology. More generally, it seems reasonable to assume that technologies better suited to the specific requirements of Rep-seq will emerge in the fairly near future and give an additional boost to this emerging field.

Bioinformatics plays a crucial role in the analysis of Rep-seq data. The aim of such analyses is often to probe the dynamic properties of the repertoire (e.g. to characterize the polyclonality of a response to a specific challenge as it changes over time), and also the fine details of an immune response (e.g. to elucidate the maturation pathway of a particular Ab of interest). Rep-seq analytics is an active area of research, with new tools regularly developed. A maintained list is available at OMICtools. The key steps that are undertaken in many Rep-seq analyses comprise (1) Preliminary sequence processing, including: NGS sequence quality control; primer masking; handling barcodes (if present); and the assembly of pair-end reads; (2) Junction analysis: the assignment of V, J and D genes (typically in descending order of confidence); and the identification of CDRs; (3) Clonal family inference, i.e. inferring which sequences arose from the same V(D)J rearrangement and (4) Maturation pathway reconstruction, i.e. inferring the unmutated ancestor and intermediates sequences for an Ab of interest.

Additionally, Rep-seq data is often integrated with structural and/or functional information about individual Abs, information that has been derived using a range of techniques including X-ray crystallography, hybridoma technology, or tandem mass spectrometry. Rep-seq of B- and T-cell repertoires has a wide range of applications. It is being used to characterise immune responses to different challenges, including vaccination (Galson *et al.*, 2014), infection (e.g. HIV Zhu *et al.*, 2013), West Nile virus (Tsioris *et al.*, 2015), and herpesviruses (Klarenbeek *et al.*, 2012), and to cancer (van Heijst *et al.*, 2013). It is also being used to help us gain a better understanding of the properties of 'normal' repertoires, such as the degree of similarity/dissimilarity between the repertoires of individuals (including twin studies (Zvyagin *et al.*, 2014), and to elucidate the impact of ageing (Rubelt *et al.*, 2012)). Rep-seq can also help us gain insights into the properties of immune dysfunction (e.g. acute Systemic Lupus Erythematosus (Tipton *et al.*, 2015) and rheumatoid arthritis (Tan *et al.*, 2014).

Conclusions

Computational immunogenetics involves the development and application of bioinformatics methods, mathematical models and statistical techniques for the study of immune system biology. The immune system composition is highly heterogenic and all the entities involved in its functionality play both centralized and de-centralized roles. The metaphor that depicts the immune system like an orchestra is tight-fitting as it really shows a clear image on the machinery that governs the immune function. Tens of different cell types and thousands of interconnected molecular pathways and signals act in real time to carry on the defence against pathogens and tumours. Systems approaches can be used to predict how the immune system will respond to a particular infection or therapeutic strategies, helping in the comprehension on how to act on an immunotherapy to enhance their effect and to reduce possible side-effects. Moreover, computational approaches are increasingly vital to understand the implications of the wealth of gene expression and epigenomics data being gathered from immune cells. The availability of dozens of immune database really helps in organizing and deciphering the huge amount of data that is collected day by day from the availability of new biotechnological approaches. Multi-scale methodologies are needed to tether molecular, cellular and organism levels, in order to gain a global vision on how the things really go. There are already such methodologies but they still suffer of complex issues related to the communications among them i.e., the scales speak different languages in terms of time and space. Computational

immunology is also required in the new challenge in the field of computational biomedicine: *in silico* trials. *In silico* trial platforms allow the simulation of the relevant individual human physiology and physiopathology in patients. Virtual populations of individuals aim to study the effects of treatments, allowing the simulation of the action of the vaccination strategies and predicting the treatments outcomes in order to have a personalized medicine approach. In the near future, *in silico* trial could predict, explore and inform of the reasons for failure should the vaccinations strategies against a determined pathology under testing found not efficient, which will suggest possible improvements, which can be rapidly explored on *in silico* platforms. Another possible benefit of the *in silico* trial platform could be the reduction of human testing: by providing a reliable prediction of the phase III outcomes on the basis of the data collected a phase II clinical trial, it will increase the confidence in investing in a phase III trial to demonstrate the efficacy in term of reduced recurrence and to drastically reduce the numerosity of the enrolled patients to obtain enough statistical power.

Biographical Sketch

Marta has a bachelor's Degree in Biology (2015) and a master Degree in Biomedical Investigation (2016) both from Universidad Complutense of Madrid. She has two years of experience in the Department of Clinical Microbiology and Infectious Diseases of the Hospital General Universitario Gregorio Marañón of Madrid. After completing her master degree Marta joined the Immumedicine Group at the School of Medicine of the Complutense University where she is pursuing her PhD, which is based on computer-assisted design of epitope-based vaccines.

Giulia Russo received the MSc degree in Pharmacy from the University of Catania, in 2014. In 2015, she started her research activities at the Department of Drug Sciences, University of Catania, in the field of computational modeling in oncology and immunology in Prof. Francesco Pappalardo's research group. Her current research interests include signalling pathways analysis, systems biology and computational biology in oncology. In 2015, she won the competition for the PhD program in biomedical and biotechnological sciences, with a particular interest in computational approaches in systems biomedicine.

Jose Luis has a Bachelor's Degree in Biotechnology (2015), from the Pablo de Olavide University, followed by a Master's Degree in Advanced Genetics, from the Autonomous University of Barcelona (2016). Then, he worked as research assistant in Severo Ochoa's Center for Molecular Biology to work on Huntington's disease. Jose Luis joined the Immunomedicine group early in 2017 to complete his PhD in T-cell immunology.

Marzio Pennisi is currently a post-doc researcher at the University of Catania, Italy. He earned his MSc. and PhD. degrees from University of Catania, in 2006 and 2010 respectively. His research topics include stochastic optimization techniques, evolutionary algorithms, constrained and unconstrained optimization and computational and mathematical methods for the simulation of the immune system. Up to now, he published more than 60 reviewed research papers. He serves the scientific community as editorial board member, reviewer and program committee member for various journals and conferences in the area of computer science, computational biology and bioinformatics.

Pedro A Reche is Chemist (1990) with a Ph.D. in Molecular Biology/Biochemistry (1995) from the University of Granada, Spain. He obtained post-doctoral training at the Department of Biochemistry of the University of Cambridge (England) (1995-1998) and the DNAX Research Institute, California, USA (1998-2001). From 2001 to 2006, he worked at the Dana-Farber Cancer Institute, Boston, MA, USA, directing the Bioinformatics cores of the Molecular Immunology Foundation and the Cancer Vaccine Center. He also held the appointment of Instructor of Harvard Medical School. Late 2006, he joined the University Complutense to establish the Immunomedicine Group. Pedro is a multidisciplinary scientist with relevant contributions on the fields of Biochemistry, Molecular Biology, Bioinformatics and Immunology. He has published over 60 articles in peer review journals that have received over 4700 citations (h-index = 28) and he is in the Editorial Board of 5 international journals. Pedro's main research lines are A) prediction of immunogenicity, B) discovery of therapeutic molecules and C) study of adaptive immune conditioning by epithelial cells.

Dr Adrian Shepherd was awarded a PhD in Neural Computing at UCL in 1995, then joined the research group of Prof. Janet Thornton as a Post-Doctoral Research Fellow to design machine learning classifiers for protein structure prediction. He joined Birkbeck, University of London as a lecturer in 2002, and was a founding member of the European ImmunoGrid Consortium. Now a Reader in Computational Biology at the Institute of Structural and Molecular Biology, Birkbeck, his research focuses on human adaptive immune response using a range of computational methods - from Next Generation Sequencing of immune repertoires (Rep-seq) to molecular dynamics simulations of antibody binding. His group collaborates with clinicians, virologists and other wet-lab research scientists to address medical problems that include the design of more effective vaccines and the stratification of patient responses to therapy. He is currently working on the adaptive immune response to several pathogens (influenza A virus, hepatitis C virus and Bacillus anthracis), to cancer (hepatocellular carcinoma and breast cancer), and to therapeutic proteins (notably replacement Factor VIII used in the treatment of hemophilia A).

Francesco Pappalardo is Associate Professor of Computer Science at the University of Catania, Italy and Visiting Professor at Metropolitan College of Boston, USA. He did research in computer operating system security. He was visiting researcher at Dana-Farber Cancer Institute in Boston (USA) and at the Molecular Immunogenetics Labs, IMGT in Montpellier (France). His major research area is on computational modelling in systems biology and medicine, with a special focus on the immune system. Up to now, Francesco Pappalardo published more than 100 reviewed research papers. He serves the scientific community as editorial board member, reviewer and program committee member for major journals and conferences in the area of computer science and computational biology.

Immunoinformatics Databases

Introduction

Immunological databases play important roles in knowledge dissemination and contribute directly to our better understanding of the mechanisms underlying the defence of human body. Without appropriate data, effective bioinformatics tools cannot be built that allow for meaningful interpretations of immunological outcomes. As of May 2017, 36 immunological databases have been described in the NAR Molecular Biology Database Collection (Galperin *et al.*, 2017). Immune sequence databases provide access to experimentally characterized immune cell sequences that are implicated in infections and autoimmunity. Immune epitope databases are a set of specialist databases that stores binding data of immune molecules. Such information is commonly used to inform the design of subunit vaccines. Here, the most important databases are reviewed.

The Immune System

The human body has developed a complex immune system against the constant threat by pathogens from the environment. The first line of defence is helmed by the innate immune system, which is a general, non-specific immunity against infection that occurs rapidly upon infection (Kimbrell and Beutler, 2001). The cells from the innate immune system recognize and respond to pathogens generically, as they have different types of receptors to recognize common features of pathogens. Hence, the effects of immunity to the host are only short-lived.

In contrast, the adaptive immune system is much more specialized, capable of a more effective elimination of the infection in the event that the pathogens escape innate immunity. The adaptive immune system, consisting of B-cells and T-cells, is shaped to recognize specific infections, resulting in long-lasting immunity (Murphy *et al.*, 2008). The lymphocytes of the adaptive immune system have a single receptor type recognizing specific chemical structures, which leads to a great diversity from the huge repertoire of immunoglobulins and T-cell receptors.

What is an Epitope?

An epitope is a localized region on the surface of an antigen that is recognized by the immune system, specifically the B- or T-cells. B-cell epitopes are antigenic determinants that interact with B-cell receptors. There are two types of B-cell epitopes – linear and non-linear. About 10% of B-cell epitopes are continuous, consisting of a linear stretch of amino acids along the polypeptide chain. Most B-cell epitopes, though, are discontinuous in nature, where distant residues are brought into spatial proximity by protein folding. Studies have shown that not all residues within a B-cell epitope are functionally important for binding, and the specificity could be reduced or eliminated by single-site amino acid substitution.

T-cell epitopes are short linear peptides that bind to T-cell receptors in association with the major histocompatibility complex (MHC) molecules. Two classes of T cells are available: 1) CD8 + T cytotoxic (Tc) cells, which recognize peptides displayed by MHC class I molecules, and 2) CD4 + T helper (Th) cells, which recognize peptides in association with MHC class II molecules (#49). Tc cells release cytotoxins which are responsible for cell lysis, and granzymes which induces apoptosis. Th1 cells produce interferon γ (IFN- γ) and tumour necrosis factor β (TNF- β) and are involved in delayed-type hypersensitivity (DTH) reactions. By contrast, Th2 cells produce interleukin 4 (IL-4), IL-5, IL-10 and IL-13, which are responsible for strong antibody responses, including the activation and recruitment of IgE antibody-producing B-cells, mast cells, eosinophils, and the inhibition of several macrophage functions. T-cell epitopes presented by MHC class I molecules are typically peptides about 8–10 amino acids long, whereas MHC class II molecules binds longer peptides of about 13–20 residues.

Major Databases

In the following section, we review the major databases that are available for immunoinformatics research. This ranges from comprehensive databases such as IEDB providing epitope data and structure information, to databases specialising in genes or MHC binding information, as well as databases focusing on sequence/structure/function with emphasis on interaction information.

IEDB

The Immune Epitope Database and Analysis Resource (IEDB; see Relevant Websites section) is a central resource for immunoinformatics, with an extensive collection of B and T cell epitopes characterized experimentally in humans, non-human primates, mice, as well as other species (Fleri *et al.*, 2017). Funded by the National Institute of Allergy and Infectious Diseases (NIAID), the database was developed in 2004 at the La Jolla Institute for Allergy and Immunology with the aim of assisting researchers in the development of novel diagnostics, therapeutics and vaccines (Fig. 1).

The database contains information on peptidic and non-peptidic epitopes, as well as T cell, B cell and MHC ligand assays, which were curated from peer-reviewed literature and researcher submitted data. Each record consists of the sequence, source organism, source antigen, and references linked to additional information which include author, title and abstract of the literature. As of June 2017, IEDB includes over 298,000 peptidic epitopes and 2500 non-peptidic epitopes from over 3600 source organisms, based on approximately 319,000 T cell assays, 393,000 B cell assays, and 601,000 MHC ligand assays. This represents over 99% of all peptidic epitope information available publicly.

IMGT

The international ImMunoGeneTics information system[®] (IMGT[®]; see Relevant Websites section) is an integrated knowledge resource for immunoglobulins, major histocompatibility, and T-cell receptors of human and other vertebrates (Lefranc *et al.*, 2015). Created at 1989 by Marie-Paule Lefranc, IMGT[®] manages the diverse and complex genes and proteins of immunoglobulin and T-cell receptors, as well as the major histocompatibility proteins polymorphism. It comprises seven databases in total: (Fig. 2).

1. IMGT/LIGM-DB is a comprehensive database of fully-annotated nucleotide sequences of immunoglobulin and T-cell receptor from humans and other vertebrates (Giudicelli *et al.*, 2006). Each sequence in the database include information on sequence identification, classification of gene and allele, constitutive and specific motif description, numbering of the codon and amino acid, and the sequence obtaining information. As of June 2017, there are over 178,000 immunoglobulin and T-cell receptor sequences from 351 species.

The screenshot displays the IEDB homepage with a navigation bar at the top containing 'Home', 'Specialized Searches', 'Analysis Resource', 'Help', and 'More IEDB'. The main content area is divided into several sections:

- Welcome:** A text box explaining that IEDB is a free resource funded by a contract from the National Institute of Allergy and Infectious Diseases, offering easy searching of experimental data characterizing antibody and T cell epitopes.
- 2017 USER WORKSHOP:** A box announcing a workshop from October 25-26, 2017, at NIAID, Rockville, MD, USA, with information available at workshop.iedb.org.
- Summary Metrics:** A table showing the following data:

Peptidic Epitopes	298,573
Non-Peptidic Epitopes	2,505
T Cell Assays	319,619
B Cell Assays	393,998
MHC Ligand Assays	601,555
Epitope Source Organisms	3,605
Restricting MHC Alleles	742
References	18,528
- START YOUR SEARCH HERE:** A central section with multiple search filters:
 - Epitope:** Radio buttons for 'Any Epitopes' (selected), 'Linear Epitope', 'Discontinuous Epitopes', and 'Non-peptidic Epitopes'. A text box for 'Exact ID' with the example 'SIINFEKL'.
 - Assay:** Checkboxes for 'Positive Assays Only', 'T Cell Assays', 'B Cell Assays', and 'MHC Ligand Assays'. A text box for 'Ex: neutralization' and a 'Find' button.
 - Antigen:** A text box for 'Organism' (example: 'influenza, peanut') and a text box for 'Antigen Name' (example: 'core, capsid, myosin').
 - MHC Restriction:** Radio buttons for 'Any MHC Restriction' (selected), 'MHC Class I', 'MHC Class II', and 'MHC Nonclassical'. A text box for 'Ex: HLA-A*02:01' and a 'Find' button.
 - Host:** Radio buttons for 'Any Host' (selected), 'Humans', 'Mice', and 'Non-human Primates'. A text box for 'Ex: dog, camel' and a 'Find' button.
 - Disease:** Radio buttons for 'Any Disease' (selected), 'Infectious Disease', 'Allergic Disease', and 'Autoimmune Disease'. A text box for 'Ex: asthma, diabetes' and a 'Find' button.
- Epitope Analysis Resource:** A section on the right with links for 'T Cell Epitope Prediction' (including MHC I Binding, MHC II Binding, MHC I Processing, and MHC I Immunogenicity), 'B Cell Epitope Prediction' (including Antigen Sequence Properties, Predict discontinuous B cell epitopes, and Discotope), and 'Epitope Analysis Tools' (including Population Coverage, Conservation Across Antigens, and Clusters with Similar Sequences).

At the bottom, there are links for 'Provide Feedback', 'Help Request', 'Solutions Center', and 'Tool Licensing Information'. A footer note states: 'Supported by a contract from the National Institute of Allergy and Infectious Diseases, a component of the National Institutes of Health in the Department of Health and Human Services. Data Last Updated: June 04, 2017'.

Fig. 1 IEDB homepage where users can start accessing data by performing queries based on epitopes, assays, antigens, MHC restriction type, hosts and diseases. IEDB. Available at: <http://www.iedb.org>.

WELCOME! to the IMGT Home page

THE INTERNATIONAL IMMUNOGENETICS INFORMATION SYSTEM®

IMGT®	IMGT®, the international ImMunoGeneTics information system® http://www.imgt.org , is the global reference in immunogenetics and immunoinformatics, created in 1989 by Marie-Paule Lefranc (Université de Montpellier and CNRS). IMGT® is a high-quality integrated knowledge resource specialized in the immunoglobulins (IG) or antibodies, T cell receptors (TR), major histocompatibility (MH) of human and other vertebrate species, and in the immunoglobulin superfamily (IgSF), MH superfamily (MhSF) and related proteins of the immune system (RPI) of vertebrates and invertebrates. IMGT® provides a common access to sequence, genome and structure Immunogenetics data, based on the concepts of IMGT-ONTOLOGY and on the IMGT Scientific chart rules. IMGT® works in close collaboration with EBI (Europe), DBJ (Japan) and NCBI (USA). IMGT® consists of sequence databases , genome database , structure database , and monoclonal antibodies database , Web resources and interactive tools .

Fig. 2 The IMGT homepage with links to the seven databases. IMGT®. Available at: <http://www.imgt.org>.

2. IMGT/MH-DB specializes in human major histocompatibility complex sequences (Robinson *et al.*, 2015). Established as a locus-specific database for the allelic sequences of the HLA genes, the database also includes official sequences specified by the World Health Organization Nomenclature Committee For Factors of the HLA System. As of June 2017, there are 12,351 HLA class I alleles, 4404 HLA class II alleles, and 178 non-HLA alleles in the database.
3. IMGT/PRIMER-DB is a database of oligonucleotides (primer) for immunoglobulin and T-cell receptor. The primers can be used for antibody single chain Fragment variable (scFv), combinatorial library design, microarray technologies and phage display. The database comprises 1864 primers from 11 species.
4. IMGT/CLL-DB is a database specializing in primary immunoglobulin sequences associated with clinical and biological data of Chronic Lymphocytic Leukemia (CLL) patients. There are current restrictions to the database for members of the IMGT/CLL-DB group.
5. IMGT/GENE-DB is a comprehensive database for immunoglobulin and T-cell receptor genes from human, mouse, rat and rabbit (Giudicelli *et al.*, 2005). The database is the international reference for the gene nomenclature of immunoglobulin and T-cell receptor, displaying gene data related to genome, allelic polymorphisms, gene expression, protein and structures. As of June 2017, the database contains 4147 genes and 5858 alleles from 24 species.
6. IMGT/3Dstructure-DB is a resource on annotated structural data of immunoglobulin, T-cell receptor, MHC and related proteins of the immune system (Ehrenmann *et al.*, 2010). With 4766 entries currently, each record provides information on the sequence, 2D structures and 3D structures.
7. IMGT/mAB-DB is a monoclonal antibodies database, providing resource on immunoglobulins or monoclonal antibodies with clinical indications, as well as fusion proteins for immune applications. As of June 2017, the database contains 722 records.

SYFPEITHI

One of the first publicly available database for MHC ligands and peptide motifs, SYFPEITHI (see Relevant Websites section) is a database of known peptide sequences bound to MHC class I and II molecules (Rammensee *et al.*, 1995). It was developed in 1999

Fig. 3 Homepage of SYFPEITHI, with links to access the database. SYFPEITHI. Available at: <http://www.syfpeithi.de>.

by Hans-Georg Rammensee's group at the Institute of Cell Biology, University of Tübingen. With over 7000 MHC ligands, motifs and T-cell epitopes, the database aims to facilitate the search for peptides and aiding in the prediction of T-cell epitopes. Manually curated from published literature, each record provides information on the source and reference (Fig. 3).

AntiJen

AntiJen (see Relevant Websites section) is a large compilation of quantitative binding data (McSparron *et al.*, 2003). Developed by Darren Flower's group at the Edward Jenner Institute for Vaccine Research, the database was developed with the aim of improving computational vaccinology for building tools to accurately predict epitopes. The database includes MHC ligand molecules and kinetics, T cell epitopes, Transmembrane Peptide Transporter and B cell epitopes, protein complexes and protein-protein interactions, as well as data peptide library, diffusion coefficient and copy numbers. With over 24,000 entries based on experimentally determined data, AntiJen is among the largest immune epitope databases available (Fig. 4).

MHCBN

MHCBN (see Relevant Websites section) is a comprehensive database on MHC binding and non-binding peptides curated from existing databases and published literature (Lata *et al.*, 2009). The database was developed by Gagendra Raghava's group at the Institute of Microbial Technology in India. With over 25,800 peptide sequences, the database provides sequence and structure data on the source proteins as well as the MHC molecules (Fig. 5).

MPID-T2

The MHC-Peptide Interaction Database-TR version 2 (MPID-T2; see Relevant Websites section) is a new generation database with information on the sequence-structure-function of T-cell receptor/peptide/MHC interactions (Tong *et al.*, 2006). First developed at National University of Singapore in 2006 by Shoba Ranganathan's group, and subsequently at the Macquarie University in 2010, the MPID-T2 contains information on all known structures of T-cell receptor/peptide/MHC and peptide/MHC complexes, emphasizing on the structural characterization. Protein interaction information such as hydrogen bonds, non-hydrogen bonds, solvent accessibility, contact residues, interface area, gap index and gap volume is also included. Manually curated and populated with data from the Protein Data Bank (PDB), the database contains 415 records from humans (282), murine (127), rat (3), chicken (2), and monkey (1), which spans across 56 alleles. The database aims to facilitate the development of tools to predict peptide binding to MHC alleles (Fig. 6).

BEID

The B-cell Epitope Interaction Database (BEID) is a repository of sequence-structure-function information on interactions of immunoglobulin-antigen (Tong *et al.*, 2008). The database contains 164 antigens, 126 immunoglobulins and 189 immunoglobulin-antigen complexes extracted from PDB where they were manually verified, classified, and then analysed for the intermolecular

Quick Search: [Help](#)

Welcome to the AntiJen Database v2.0.

AntiJen v2.0, is a database containing quantitative binding data for peptides binding to [MHC Ligand](#), [TCR-MHC Complexes](#), [T Cell Epitope](#), [TAP](#), [B Cell Epitope](#) molecules and [immunological Protein-Protein interactions](#). Most recently, AntiJen has included [Peptide Library](#), [Copy Numbers](#) and [Diffusion Coefficient](#) data. All entries are from published experimentally determined data. The database currently holds over 24,000 entries. No data in AntiJen is from prediction experiments..

[JenPep](#)^{1,2} established a basic system which has now undergone major advancements. **AntiJen v2.0** not only contains a wider spectrum of data but also demonstrates superior search capabilities. The expanded and updated AntiJen database currently accommodates data and look-up access for:

- MHC Ligand molecules and MHC Ligand kinetics,
- T Cell Epitope, TAP and B Cell Epitope molecules,
- Protein-Protein interactions and Protein complexes,
- Peptide Library, Diffusion Coefficient and Copy Numbers data.

Development of sophisticated search mechanics incorporates the flexibility to conduct a very detailed search or a broad search from a single interface. For example,

- the search engine can accept epitope strings containing variable amino acid positions,
- specific amino acid alternatives can be requested in any epitope string,
- an optional filter can be used to target experimental data of interest,
- delimiting windows can be used to narrow searches further by epitope length or data size.

Other novel search functionality includes:

- Quick Search, this provides instant cross-category database access;
- Keyword Search, AntiJen may be searched using keyword input alone .

interactions. Each record contains interaction information on gap index, gap volume, interface area, solvent accessibility, contact residues, hydrogen bonds and non-hydrogen bonds.

CED

The Conformational Epitope Database (CED; see Relevant Websites section) is a specialist database on conformational B cell epitopes (Huang and Honda, 2006). Manually curated from peer-reviewed literature, each entry contains information on the location and composition of the epitope, immunological property, source antigen and corresponding immunoglobulin. As of June 2017, the database contains 225 entries from protein antigens, nucleic acids, glycans and lipids, derived from various sources.

DFRMLI

The Dana-Farber Repository for Machine Learning in Immunology (DFRMLI; see Relevant Websites section) is a database specializing in standardized datasets for the application of machine learning in immunology (Zhang *et al.*, 2011). Processed specifically for the development of machine learning tools for use in epitope prediction, the repository provides standard datasets of experimentally validated binding affinities of HLA-binding peptides mapped onto a common scale.

MHCBN Version 4.0

ing with TAP. The database is cross-linked to NCBI, Swiss-Prot, PDB, OMIM and GenBank.

The MHCBN is a curated database consisting of detailed information about Major Histocompatibility Complex (MHC) Binding, Non-binding peptides and T-cell epitopes. The version 4.0 of database provides information about peptides interacting with TAP and MHC linked autoimmune diseases. This database is Developed by [Dr Raghava's Group](#), at [Bioinformatics Centre, Institute of Microbial Technology, Chandigarh, INDIA](#).

What MHCBN can do for you

Resources	The database provides information about allele specific MHC binding peptides, MHC non-binding, TAP binding, TAP non-binding peptides and T-cell epitopes reported in literature	
Hypertext Links	Antigenic Protein	Source or Antigenic proteins are linked to SWISS-PROT database
	MHC Sequence	MHC Allele sequence are hyperlinked to IMGT/HLA-DB
	3D-Structure	The hypertext link has been made to Protein Databank(PDB) if any identical/related peptide/MHC protein is available in PDB.
	Diseases	The MHC linked diseases has been hyperlinked to OMIM.
	References	For full information references are linked to PubMed
Web Tools	Query Searching	The web server has tools(General query &Peptide search) to extract all information from the fields of database.
	TAP Search	The tool has been designed for searching the part of sequence interacting with TAP.
	Peptide Mapping	This option allows mapping of binders, non-binder and T-cell epitope in query protein
	Dataset Creation	This allows Creation of Allele specific peptide datasets useful for developing prediction methods
	Similarity Search	This option allows BLAST search of query protein sequence against antigenic and MHC proteins in database

The Database can be accessed from [Mirror site at IAMS](#)

MPID-T2

HOME SEARCH STATISTICS PATTERNS ALIGNMENT REFERENCES CONTACT US HELP

About MPID-T2:

The MHC-Peptide Interaction Database-TR version 2 (MPID-T2) is a new generation database for sequence-structure-function information on T cell receptor/peptide/MHC interactions. It contains all known crystal structures of TR/pMHC and pMHC complexes, with emphasis on the structural characterization of these complexes.

MPID-T2 will facilitate the development of algorithms to predict whether a peptide sequence will bind to a specific MHC allele forming a pMHC agonist which will consequently be recognized by a particular TR leading to T cell activation for immune response. The database has been populated with data from the Protein Data Bank(PDB). The data from PDB is manually verified and classified, after which each structure is analysed for atomic interactions relevant to pMHC and TR/pMHC complexes.

The intermolecular hydrogen bonds are calculated using the program [HBPLUS](#), gap volume is pre-computed using the program [SURFNET](#) and change in interface area due to complex formation is calculated based on accessible surface area calculation performed by the [NACCESS](#) program for structures released until December 2006 and by the [ICM](#) program for structures released after December 2006. Gap index is calculated using the values for gap volume and interface area. Schematic diagrams of the pMHC and TR/pMHC interactions based on the plotting program [LIGPLOT](#) are also available. The peptide consensus patterns available in MPID-T2 are generated using the program [WEBLOGO](#).

MPID-T2 (November 2010 update) contains 415 entries from five MHC sources (Human:282, Murine:127, Rat:3, Chicken:2 and Monkey:1), spanning 56 alleles. [353](#) of which are pMHC structures and [62](#) TR/pMHC complexes. MHC-I (class I pMHC and TR/pMHC) complexes number 352 while 63 structures are from MHC-II (class II pMHC and TR/pMHC) complexes. On the whole, 327 entries are non-redundant (279 from MHC-I and 48 from MHC-II complexes). Among the TR/pMHC structures 50 are MHC-I and 11 are MHC-II structures. Included in this version are non-classical structures and complexes with non-standard residues. MPID-T2 is updated on a quarterly basis. To view the distribution graphically [click here](#). To visualize the structural alignment you need [Chime](#) or [Java](#) plug-in for [Jmol](#). MPID-T2 is best viewed using Internet Explorer.

MPID-T2 Team:

MPID-T2 is proudly brought to you by [Javed Mohammed Khan](#), [Harish Reddy Cheruku](#), [Joo Chuan Tong](#) and [Shoba Ranganathan](#)

IPD

The Immuno Polymorphism Database (IPD; see Relevant Websites section) is a compilation of specialist databases associated with the study of gene polymorphisms in the immune system (Robinson *et al.*, 2013). It was developed in 2003 from a collaboration between the European Bioinformatics Institute (EBI) and the HLA Informatics Group of the Anthony Nolan Research Institute. The IPD comprises four databases: (Fig. 7).

1. IPD-KIR provides a repository on human Killer-cell Immunoglobulin-like Receptors (KIR) sequences. There are over 600 alleles in the database, coding for more than 320 unique sequences.
2. IPD-MHC is a centralised database of MHC sequences from different species. Manually curated by field experts, the database now contains over 4000 alleles from 47 species of non-human primates, as well as other species including canines, felines, cattle, teleost fish, rats, sheep, and swine.

Fig. 7 The IPD homepage with links to four specialist databases.

Fig. 8 Homepage of HIV Molecular Immunology Database with links to search interfaces.

3. IPD-HPA details data on the human platelet antigens (HPA). The database provides information on the HPA as well as additional background information.
4. IPD-ESTDAB is the European Searchable Tumour Line Database and Cell Bank for immunologically characterized melanoma cell lines. The database provides a search facility for HLA typed, immunologically characterized tumour cells.

HIV Molecular Immunology Database

The HIV Molecular Immunology Database (see Relevant Websites section) is an annotated database of HIV-1 cytotoxic and helper T-cell epitopes, and immunoglobulin binding sites. The database is funded by the Division of AIDS, National Institute of Allergy and Infectious Diseases and developed by the Los Alamos National Laboratory. The data is extracted from HIV immunology literature, and includes information on immunoglobulin sequence, escape mutations, cross-reactivity, T-cell receptor usage, functional domains overlapping with epitopes, immune response among others. As of June 2017, there are 905 HIV-1 cytotoxic T cell epitopes, 1023 HIV-1 helper T-cell epitopes and 1448 immunoglobulin binding sites in the database (Fig. 8).

Discussion

The immunoinformatics field has matured over the past decade, with the creation of many high-quality immunological databases available publicly. Many of the databases discussed above contain well-curated and comprehensive data on MHC ligands and immune epitopes, including both naturally processed peptides as well as synthetic peptides available on IEDB. Some of the databases such as IEDB, AntiJen, MHCBN, MPID-T2 and BEID also include information on the structure and protein-protein interactions which provides much more detail to study individual binding interactions. On the other hand, there are also specialized databases such as DFRMLI in addition to IEDB and IMGT, which provide training datasets with large number of MHC-peptide binding data to facilitate the development of machine learning approaches for epitope prediction. While there are a multitude of databases available, the challenge remains to update the database with new information regularly so that more tools would be able to utilize the rich resource to advance the field of immunoinformatics.

Study of Human Antibody Responses From Analysis of Immunoglobulin Gene Sequences

Katherine J.L. Jackson, Garvan Institute of Medical Research, Darlinghurst, NSW, Australia

© 2019 Elsevier Inc. All rights reserved.

Introduction

Antibodies are a crucial component of the immune system and the genes that encode antibodies are subject to more manipulation and modification than any other human genes. The many processes that occur during antibody ontogeny are captured within the sequence of the rearranged immunoglobulin genes. The study of the sequences of these genes therefore provides a window into not only the antigen response but also into the underlying genetics of the person who produced the response. Sequencing technologies that capture millions of immune receptor gene transcripts offer a means for high resolution analysis of the antibody response in contexts ranging from responses to infection (Wu *et al.*, 2011; Parameswaran *et al.*, 2013; Liao *et al.*, 2013) and vaccination (Wang *et al.*, 2015; Jackson *et al.*, 2014; Galson *et al.*, 2015; Ellebedy *et al.*, 2016; Truck *et al.*, 2015), to autoimmunity and immune deficiency (Roskin *et al.*, 2015), in allergy (Hoh *et al.*, 2016; Wang *et al.*, 2014; Levin *et al.*, 2016) and in lymphoid cancers (Boyd *et al.*, 2009; Faham *et al.*, 2012).

Each antibody protein in the human is comprised of four polypeptide chains – two identical heavy chains encoded by an immunoglobulin heavy chain (IGH) gene and two identical light chains encoded by either an immunoglobulin kappa (IGK) or lambda light chain (IGL) gene (Fig. 1) (Tonegawa, 1983). Each polypeptide chain is broadly divided into two regions; the variable region and the constant region. The variable portion of immunoglobulin genes are formed by a series of genomic rearrangements within each B cell's genome at the heavy (chromosome 14 (Croce *et al.*, 1979)) and light chain loci (kappa: chromosome 2, lambda: chromosome 22 (McBride *et al.*, 1982)) that bring together several gene segments to form an immunoglobulin gene (Tonegawa, 1983) (Fig. 1(A)). The resulting gene is often termed a 'rearranged' immunoglobulin gene in order to differentiate it from the unrearranged or 'germline' gene segments within the immunoglobulin gene loci that are the building blocks from which functional antibodies are created. The process of genomic recombination allows for a vast diversity of antibody proteins to be generated from a relatively small number of variable (IGHV), diversity (IGHD) and joining (IGHJ) gene segments for the heavy chain and variable (IGKV/IGLV) and joining (IGKJ/IGLJ) gene segments for the light chains. The same V(D)J recombination mechanism also forms the T cell receptor (TCR) gene repertoire (Davis, 1990).

The variable region of an immunoglobulin protein provides the antigen specificity. It can be further sub-divided into four structurally important framework regions (FR1, 2, 3, 4) and three diverse complementarity determining regions (CDR1, 2, 3) that tend to contact the antigen (Chothia and Lesk, 1987). Immunoglobulin protein function is dictated by the constant region, encoded by the heavy chain constant region (IGHC) gene, which determines the isotype or subclass of the immunoglobulin (Schroeder and Cavacini, 2010). IGHG exons are associated with the variable region at the level of mRNA transcription and each isotype class and subclass has varying in its functional capabilities. Prior to antigen exposure, naïve B cells express their VDJ rearrangement in association with both IgM and IgD through alternative mRNA splicing (Fig. 1(D)). Following antigen encounter, further genomic changes, termed class switch recombination (CSR), alter the associated constant region by deletion of IGHG genes from the genome and allowing expression of IgG subclasses (IgG3, IgG1, IgG2, IgG4), IgA subclasses (IgA1, IgA2), or IgE (Fig. 1(D)). The constant region also determines if paired heavy and light chains are secreted from the B cell as antibodies, or if they are membrane bound and act as B cell receptors (BCRs). This is based on whether the constant region includes a terminal secretory (antibodies) or trans-membrane domain (BCRs). Light chains also have constant regions encoded by IGKC or IGKL genes but these do not undergo CSR.

In addition to CSR, following encounter with an antigen to which the BCR can bind, immunoglobulin genes will also undergo affinity maturation (Fig. 1(E)) (Eisen, 2014). This is driven by a mutation process termed somatic hypermutation (SHM) because the mutations are introduced within the V(D)J gene rearrangement at a rate of 10^5 to 10^6 above the normal background somatic mutation rate (Weigert *et al.*, 1970) (Bernard *et al.*, 1978). The point mutations introduced within the V(D)J may be positively selected when they improve the interaction between the antigen and the immunoglobulin and negatively selected when they are deleterious. CSR and affinity maturation occur in the context of the B cell clonal expansion whereby the initial B cell that expressed an immunoglobulin with some specificity for antigen divides and each daughter cell inherits the immunoglobulin rearrangement, but may acquire further SHM and undergo further class switch, to build a B cell clonal lineage.

Diversification of Immunoglobulin Genes

The diversity of the human antibody repertoire within a single person is predicted to be as high as 10^{11} unique antibodies (Glanville *et al.*, 2009). Given that a human genome includes fewer than 20,000 protein-coding genes (Ezkurdia *et al.*, 2014), it is not possible for a single gene for each unique antibody to be maintained within the germline genome, rather a diverse immunoglobulin repertoire is generated through processes that involve rearrangements and modifications to the genomes of single immune cells (Tonegawa, 1983). Immunoglobulin diversification processes can be broadly divided into 'combinatorial' and
